CONTRIBUTORS TO THIS NUMBER

- EDWARD L. BAUER, M. D., Professor of Children's Diseases, Jefferson Medical College; Pediatricist, Jefferson Hospital and the Hospital for Contagious Diseases.
- P. BROOKE BLAND, M. D., Professor of Obstetrics, Jefferson Medical College.
- CHARLES L. BROWN, M. D., Professor of Medicine and Head of the Department of Medicine, Temple University Medical School and Hospital.
- AARON CAPPER, M. D., Demonstrator in Pediatrics, Jefferson Medical College; Associate Pediatricist, Jewish Hospital.
- CHARLES C. CHAPPLE, M. D., Instructor in Pediatrics, University of Pennsylvania School of Medicine; Assistant Attending Physician, Abington, Chestnut Hill, Germantown, and Presbyterian Hospitals.
- BERNARD ISAAC COMROE, M. D., Instructor in Medicine, University of Pennsylvania School of Medicine and Evans Dental Institute of the University of Pennsylvania; Assistant Ward Physician, Hospital of the University of Pennsylvania.
- THOMAS J. COSTELLO, M. D., Assistant Demonstrator of Gynecology, Jefferson Medical College; Gynecologist and Obstetrician, Out-patient Department, Bryn Mawr Hospital.
- GARFIELD G. DUNCAN, M. D., Associate in Medicine, Jefferson Medical College; Chief of Metabolic Clinic and Assistant Physician, Pennsylvania Hospital.
- JOHN DURKIN, M. D., Assistant Physician, Medical and Metabolic Out-Patient Departments, Pennsylvania and Bryn Mawr Hospitals.
- ARTHUR FIRST, M. D., Associate in Obstetrics, Jefferson Medical College.
- THOMAS FITZ-HUGH, JR., M. D., Assistant Professor of Clinical Medicine, University of Pennsylvania School of Medicine; Chief of Hematology Section, Hospital of the University of Pennsylvania.
- GEORGE H. FONDÉ, M. D., Instructor in Dermatology and Syphilology, University of Pennsylvania School of Medicine.
- JOHN MCK. MITCHELL, M. D., Associate in Pediatrics, University of Pennsylvania School of Medicine; Assistant Visiting Physician, University of Pennsylvania Hospital; Attending Pediatrician, Bryn Mawr Hospital.
- HENRY K. MOHLER, M. D., Associate Professor of Medicine, Jefferson Medical College; Assistant Physician, Jefferson Hospital.
- JOSEF B. NYLIN, M. D., Assistant Professor of Physical Therapy, Woman's Medical College of Pennsylvania; Associate in Physical Therapy, University of Pennsylvania School of Medicine; Chief of Clinic, Department of Physical Therapy, Hospital of the University of Pennsylvania.
- ABRAHAM M. ORNSTEIN, M. D., Assistant Professor of Neurology, University of Pennsylvania School of Medicine; Neurologist, University, Philadelphia General, and Jewish Hospitals.
- FRANKLIN L. PAYNE, M. D., Assistant Gynecologist, Hospital of the University of Pennsylvania; Gynecologist, Chestnut Hill Hospital; Gynecologist and Obstetrician, Pennsylvania Hospital.
- P. S. PELOUZE, M. D., Assistant Professor of Urology, University of Pennsylvania School of Medicine.
- O. H. PERRY PEPPER, M. D., Professor of Medicine, University of Pennsylvania School of Medicine.
- DONALD M. PILLSBURY, M. D., Assistant Professor of Dermatology and Syphilology, University of Pennsylvania School of Medicine.
- MITCHELL I. RUBIN, M. D., Physician, Children's Hospital of Philadelphia.
- FREDERICK S. SCHOFIELD, M. D., Associate in Urology, Hospital of the University of Pennsylvania.
- O. NORRIS SMITH, M. D., Assistant Instructor in Pathology, University of Pennsylvania; Resident in Pathology, Hospital of University of Pennsylvania.
- MARTIN J. SOKOLOFF, M. D., Demonstrator of Medicine, Jefferson Medical College; Visiting Physician, White Haven Sanatorium, White Haven, Pa.
- JOSEPH STOKES, JR., M. D., Assistant Professor of Pediatrics, University of Pennsylvania School of Medicine; Associate Physician-in-Chief, Children's Hospital.
- MARGARET CASTEX STURGIS, M. D., Clinical Professor of Gynecology, Woman's Medical College of Pennsylvania; Associate Gynecologist, Hospital of the Woman's Medical College of Pennsylvania; Gynecologist, Woman's Hospital of Philadelphia; Assistant Gynecologist and Obstetrician, Philadelphia General Hospital.
- NORRIS W. VAUX, M. D., Clinical Professor of Obstetrics, Jefferson Medical College; Obstetrician and Gynecologist-in-Chief, Philadelphia Lying-In and Maternity Department of the Pennsylvania Hospital.
- THEODORE S. WILDER, M. D., Associate in Pediatrics, University of Pennsylvania School of Medicine; Chief of Pediatric Services, St. Christopher's and Germantown Hospitals; Visiting Pediatrician, Abington Memorial Hospital.
- MICHAEL G. WOHL, M. D., Associate Professor of Medicine, Temple University School of Medicine; Assistant Visiting Physician, Philadelphia General Hospital; Visiting Physician, Northern Liberties Hospital.

SYMPOSIUM ON FEVERS OF OBSCURE ORIGIN IN. CHILDHOOD

The following clinics are included in this Symposium:

Joseph Stokes, Jr.: INTRODUCTION.

Mitchell I. Rubin: FEVERS DUE TO UPPER RESPIRATORY INFECTIONS.

Charles C. Chapple: FEVERS DUE TO LOWER RESPIRATORY INFECTIONS.

John McKenney Mitchell: FEVERS OF ABDOMINAL ORIGIN.

Mitchell I. Rubin: FEVERS DUE TO DISEASES OF THE URINARY TRACT.

T. S. Wilder: FEVERS DISCUSSED FROM THE STANDPOINT OF CENTRAL NERVOUS
SYSTEM DISEASE.

Charles C. Chapple: FEVERS DUE TO MISCELLANEOUS CONDITIONS.

SYMPOSIUM ON FEVERS OF OBSCURE ORIGIN IN CHILDHOOD

INTRODUCTION

JOSEPH STOKES, JR.

EVERY practitioner of medicine is faced many times yearly with a puzzling infant or child who shows day after day an elevation of temperature of obscure origin. Each morning the physician's hopes may rise as the parents report a temperature approaching normal, and each evening they are dashed again as the eyes of the parents search his face for any sign of hope or recognition of the cause.

Professional reputation and the regard of a community for the practitioner depend more upon the management of such cases than upon almost any other phase of medical practice.

Equally puzzling, but ordinarily not as momentous for professional reputation, are the obscure fevers of short duration, one, two, or three days, which frequently rise to alarming heights with great rapidity, and then as rapidly drop toward a normal figure. It is perhaps in this latter group of short duration more than in the former, that the child frequently is "cured" without a rational explanation for either the fever or the "cure." For the parent the rapid "cure" is usually sufficient evidence to quiet whatever doubts he may have had concerning the practitioner's guarded explanations of the cause.

Driven more by the apparent necessity of presenting some valid explanation to the parents rather than to himself the practitioner will often announce the diagnosis without mentioning alternatives, which he fears the parents may regard

as lack of knowledge. In such a position he may feel the necessity of bolstering and confirming from day to day his original diagnosis, which is possibly incorrect, and in this way he not only becomes less alert, but even shuts his mind to the correct diagnosis, or to the facts which may lead to a correct diagnosis. This type of intellectual dishonesty is readily acquired and too often practiced inasmuch as parents, usually ignorant of medical facts, appear to be more readily satisfied and relieved by a single definite diagnosis announced with considerable confidence.

Certainly when the origin of the fever is obscure the primary emphasis to the parents should be placed upon the importance of continued thorough investigation by all laboratory and clinical means available. Emphasis also upon the more probable causes is obviously essential, but the parents should never be unaware of the physician's lack of complete certainty.

It is the observation of keen practitioners who have had long and valuable experience that one of the most frequent, if not the most frequent, difficulty in the diagnosis of fevers of obscure origin is not the lack of a careful examination, nor the failure to analyze carefully signs and symptoms, but the fact that the correct cause of the condition does not happen to occur to them. At times the occurrence of the fortunate thought almost appears to be a matter of mere chance. And yet it is well recognized that the practitioner who has had excellent training in pathology at the beginning of his career and who continues to frequent the mortuary is far more apt to keep in mind the variety of diagnoses that must always be carefully reviewed under such circumstances. In the diagnosis of fevers of obscure origin an intimate acquaintance with pathological variations in the body organs is often of greater importance than the examination of the patient, however important the latter may be.

The objectives then of this symposium are essentially the following:

1. To present in reasonable order the names of a variety of diagnoses which might not readily occur to every practi-

tioner having difficult diagnostic problems in which fever of obscure origin is the outstanding feature.

2. To review under each diagnosis or group of diagnoses a few facts of outstanding clinical importance.

INDEX OF DIAGNOSES

FEVERS DUE TO UPPER RESPIRATORY INFECTIONS

1. The common cold.
2. Tonsil and adenoid infection.
3. Paranasal sinus infection.
4. Retropharyngeal abscess.
5. Cervical lymphadenitis.
6. Otitis media and mastoiditis.

FEVERS DUE TO LOWER RESPIRATORY INFECTIONS

1. Pneumonia.
2. Influenza.
3. Diaphragmatic pleurisy.
4. Encapsulated empyema.
5. Multiple lung abscess.
6. Bronchiectasis.
7. Mediastinal glands.
8. Mediastinal Hodgkin's disease.
9. Mediastinal abscess.
10. Tuberculosis.

FEVERS OF ABDOMINAL ORIGIN

Cases in which fever is of long duration and of variable degree:

Abdominal tuberculosis:

1. Intestinal tuberculosis.
2. Tuberculous peritonitis.
3. Tuberculosis of the mesenteric lymph nodes.

Cases of acute febrile illness in which fever is a predominant symptom and in which signs point only indefinitely to the abdomen:

1. Typhoid fever and paratyphoid fever.
2. Bacillary dysentery.
3. Amebic dysentery.
4. Ulcerative colitis.

Cases with abrupt onset and symptoms point to an acute surgical abdomen:

1. Acute appendicitis.
2. Chronic appendicitis.
3. Peritonitis.
4. Primary pneumococcic or streptococcic peritonitis.

5. Abscesses in the abdominal region.
6. Subphrenic abscess and liver abscess.
7. Acute pancreatitis.

FEVERS DUE TO DISEASES OF THE URINARY TRACT

1. Pyuria (pyelitis).
2. Carbuncle or multiple abscesses of the kidney.
3. Perinephric abscess.
4. Tuberculosis of the kidney.
5. Cystitis.
6. Urinary calculi.
7. Neoplasms.

FEVERS DISCUSSED FROM THE STANDPOINT OF CENTRAL NERVOUS SYSTEM DISEASE

1. Meningococcic meningitis.
2. Tuberculous meningitis.
3. Meningitis due to streptococcus, staphylococcus, pneumococcus, Pfeiffer's bacillus, colon bacillus, and other common organisms.
4. Poliomyelitis.
5. Encephalitis.
6. Acute lymphocytic meningitis.
7. Acute lymphocytic chorio-meningo-encephalitis.
8. Syphilitic meningitis.
9. Brain abscess.
10. Pachymeningitis.
11. Mechanical factors.
12. Toxic drugs.
13. Miscellaneous conditions apparently acting directly on the brain.

FEVERS DUE TO MISCELLANEOUS CONDITIONS

Diseases of the newborn:

1. Dehydration fever.
2. Sepsis of the newborn.

Diseases of infancy:

1. Teething.
2. Roseola infantum.
3. Scurvy.

Acute diseases with joint involvement:

1. Osteomyelitis.
2. Rheumatic fever.

Diseases chiefly involving the blood.

1. Leukemia.
2. Acute infectious mononucleosis.
3. Purpura.

INTRODUCTION

7

4. Subacute bacterial endocarditis.

5. Sickle cell anemia.

Chronic diseases:

1. Malaria.

2. Hodgkin's disease.

3. Undulant fever.

Infections due to animal contact:

1. Psittacosis.

2. Tularemia.

The more unusual diseases:

1. Rocky Mountain spotted fever.

2. Typhus.

3. Rat-bite fever.

4. Relapsing fever.

Miscellaneous causes:

1. Mechanical prevention of evaporation.

2. Abscessed teeth.

FEVERS DUE TO UPPER RESPIRATORY INFECTIONS

MITCHELL I. RUBIN

By far the commonest cause of obscure fever in childhood is infection in the upper respiratory tract. The "obscurity" of the fever is usually of short duration, for repeated careful examinations over a period of time most often throw light upon the etiological factors.

1. **The Common Cold.**—It has been facetiously said that the doctor who could not at least find an infected throat to account for the fever is a poor physician, yet many an attack of obscure fever goes undiagnosed simply because the physician fails to examine the throat of the child. Frequently one is called into the out-patient clinic to help in the diagnosis of a child presenting an obscure fever where the cause lay in an infected throat which was not examined. While it is true that the examination of the throat in an infant or child may be difficult due to the accumulation of secretion or to the perverseness of the patient, yet certainly the vast majority of brief febrile bouts in this age group are due to infections in the nasopharynx. Often for twenty-four to thirty-six hours after the onset of fever in cases of so-called "colds" the only inflammation of the mucous membrane in the upper respiratory passages that may be demonstrated occurs in the nose and conjunctivae. At this stage the pharynx not infrequently appears normal. It seems wise that the examination of the upper respiratory tract in children should include the study of the nose with electrically lighted nasal speculum. The large size speculum of the usual otoscopic set is useful for this purpose. Attacks of prolonged obscure fevers in childhood most frequently result from or are continuations of this so-called "simple cold."

2. **Tonsil and Adenoid Infection.**—The frequency with which a residual tonsillar infection is the basis for prolonged obscure fever is problematical. Certainly there are many instances of this, but just as assuredly, there are many more where the tonsils are held at fault and where tonsillectomy is performed without relief.

How and when can we consider the tonsils as the cause of the unexplained fever when examination fails to find some other etiological factor? How can chronic disease of the tonsils be recognized?

While growth of lymphoid tissue is dependent upon individual and familial variation and upon the state of nutrition (the well-nourished children having larger lymphoid structures than those undernourished), it is generally held that chronic infection of the tonsils, adenoids, or other lymphoid structures in the nasopharynx produces hypertrophy. Certainly not all enlarged tonsils or adenoids are chronically infected, and again, chronic infection may exist in these structures when they appear small. The small buried and scarred tonsil has often proved to be the focus of infection which was producing a low-grade fever. More important than the size of the tonsil alone in making one suspicious of chronic infection here is the history of repeated "sore throats" and other associated pathological findings. Palpation of the tonsil has been recommended to determine the amount of adhesions and the degree of burying. However, this is not a very satisfactory procedure. The presence of chronically reddened anterior pillars and more especially chronic enlargement of the cervical lymph nodes is indicative of tonsillar infection. Enlargement of the so-called "tonsillar node" which is situated just below the angle of the jaw is of great diagnostic importance in indicating chronically diseased tonsils. Cultures taken from the tonsillar surface have not proved of value in determining chronic infection of this organ. Some clinicians feel that when the tonsil surface is smooth and the normal crypts are not seen that chronic infection in the tonsil is most likely. Remote disease such as rheumatic infections and nephritis are said to be indications of an

infection in the tonsils, or in some other area of the upper respiratory passages. Chronic infection of the tonsils in most instances is not associated with continued pyrexia but often it does produce a low-grade intermittent fever. The degree of fever produced will vary with the individual child. Some children have a more stable temperature regulation than others. The neurotic, highly emotional child will respond to simple infections with much more fever than would the more phlegmatic child. It is to be remembered that the daily fluctuations of the normal body temperature are between 1° and $1\frac{1}{2}^{\circ}$ F. The emotional child without any infection whatsoever, may have a wider daily fluctuation in body temperature, anywhere from 1° to 2° F. The fluctuations in the temperature curve occur above and below the normal base line of 98.6° F.

Whether chronic infection of the adenoids alone will produce continued fever is not clear. Infection of these structures is most often associated with infection of the tonsils or result from infection of the sinuses which by producing a postnasal "drip" infects the adenoids.

There occurs not infrequently, especially in children where tonsillectomy and adenoidectomy have been performed early in life, some hypertrophy of the lymphoid tissue on the post-pharyngeal wall. These nodules of lymphoid tissue often become infected directly or as a result of a postnasal drip from infected sinuses. Small ulcerations appear in these lymphoid nodules and remain for long periods. Dr. Edward H. Campbell, the Otolaryngologist to the Children's Hospital, is of the opinion that this type of lymphoid infection can produce a prolonged low-grade fever which will subside after removal of this tissue. He believes that this infected tissue is best removed by electrocoagulation.

3. Paranasal Sinus Infection.—Probably the second commonest cause of low-grade obscure fever in children is paranasal sinusitis. At early age periods infection of certain of the sinuses need not be considered. The time of their development, however, is quite irregular. The ethmoid sinuses are well developed at birth and as a result of this early develop-

ment they are commonly the seat of infection early in infancy. The maxillary sinus which is probably the second most commonly infected sinus is present at birth but develops a little later than does the ethmoid sinus. The frontal sinuses and the sphenoidal sinuses are rarely infected before the seventh year of life. During each attack of a so-called "cold" there must be some involvement of the paranasal sinus which clears when the "cold" subsides.

It has been more recently demonstrated that the etiological agent in inciting a "cold" is a filtrable virus. It has also been suggested that the more severe symptoms resulting from a simple "cold" are due to certain pathogenic bacteria which become active due to the presence of the virus. It is these secondarily invading bacteria which ultimately produce chronic infection in the sinuses following one or more colds, or one of the acute exanthemata. Once the sinuses become infected they only slowly clear up. During the acute phase of sinusitis the cause of the resulting fever is rarely obscure. There is usually in this phase of the disease a profuse nasal discharge appearing anteriorly or as a postnasal drip. It may be unilateral but is most often bilateral. There is almost always an associated rhinitis. If the opening to the sinus is blocked, the symptoms are more acute. Tenderness and edema over the involved sinus are usually seen in the acute phase only, and then not always. When the ethmoids are involved edema and redness appear at the inner side of the eye and base of the nose. Both the upper and lower lids may become involved. Older children complain of pain over the involved sinus. The fever during this acute phase is not unlike that seen in acute tonsillitis, subsiding after a few days. If the acute infection fails to clear or if repeated acute attacks occur a chronic sinusitis develops, often with a low-grade fever accompanying it. As with chronic tonsillitis, fever is usually not a symptom of chronic sinusitis. The younger the child the more likely is he to have fever with this condition, and the less acute the process the lower is the febrile response. The temperature curve usually shows daily afternoon fluctuations up to

100° or 100.5° F. rectally. This may persist for weeks or longer, especially during the winter months when frequent mild exacerbations are occurring.

After all *other possible causes for the fever* have been exhausted without avail, the sinuses should be carefully investigated, more especially if there is a history of frequent "colds." The physical signs mentioned as occurring during the acute stage are usually not seen here. The x-ray in older children has been of great help in localizing the infection, but in younger children it has not been so helpful. It has been claimed that (by demonstration through x-ray examination) if retardation in the normal sinus development has occurred, one can assume that chronic infection in the sinuses exists. However, because of the normal irregular development of the sinus this would be of value only in the long standing cases. The most accurate diagnosis is made by a careful nasopharyngoscopic examination performed by a rhinolaryngologist. Transillumination in the young child is unsatisfactory. Often the diagnosis can only be made by sinus puncture with the release of pus. The postnasal drip of mucopus so often seen, in most instances arises from infection in the sinuses. It is the opinion of the rhinolaryngologists in the clinic of the Children's Hospital that the adenoids rarely produce any of this postnasal drip. A unilateral optic neuritis or local disease of the bone or eye has often been the clue to a hidden sinus infection.

A unilateral nasal infection due to a foreign body or some other local disease may be a cause of an obscure fever.

4. Retropharyngeal Abscess.—We have seen many cases of prolonged unexplained fever where ultimately a retropharyngeal abscess proved to be the cause. When the abscess is so situated or is of such size as to produce respiratory obstruction or difficult swallowing the diagnosis is not obscure. When the swelling does not produce these signs the diagnosis is not so obvious. The origin of this abscess is in the retropharyngeal lymph nodes. At times the infection in the node does not proceed on to suppuration and remains as a retropharyngeal lymphadenitis, later subsiding with a disappear-

ance of the mass. Suppuration may take place, progressing until the entire retropharyngeal space is one large abscess, even burrowing down into the mediastinum. The smaller the mass the fewer the symptoms. Usually the mass is to one side of the median line. When the nodes high up in the retropharynx are involved, nasal obstruction alone is present. When the nodal involvement is lower, swallowing is interfered with and the child gurgles his saliva. When the larynx is compressed respiratory distress is obvious. All cases of stridor should be investigated for the presence of a retropharyngeal abscess. Another striking sign is marked localized cervical gland enlargement occurring in the region of the "tonsillar" node. Often this mass presents a deep fluctuation. However, when this latter sign is present the fever is not obscure. Most retropharyngeal abscesses occur under three years of age. Those due to cervical Pott's disease present their swellings in the median line. α -Ray examination is of great help in demonstrating a retropharyngeal swelling (the trachea bulges forward) or bone disease where present. In the smaller retropharyngeal abscesses, unless this condition is suspected as a cause of low grade fever it is often undiagnosed. Digital examination is the most reliable diagnostic procedure. Care should be exercised not to open the child's mouth too widely or depress the tongue too forcefully during the examination since we have seen several cases of sudden asphyxia from this.

5. Cervical Lymphadenitis.—When acute cervical lymphadenitis exists the cause for the fever is not obscure. This condition is mentioned here only because not infrequently there is a failure to appreciate the disturbance and amount of fever which acute adenitis may cause in children. The acute adenitis is almost always secondary to acute infections in the nasopharynx. However, not infrequently the primary infection has long since subsided and there remains only the telltale lymphadenitis. Even though suppuration does not develop, fever may persist for weeks or months as long as the glands remain enlarged. This prolonged fever often results in

many consultations where each clinician after careful study is forced to conclude that the only cause for the persistent fever is the adenitis.

The temperature which is usually remittent may be slight or may vary several degrees. In young children stiffness of the neck or torticollis may result as a protection to prevent irritation of a deep seated infected lymph node. The younger the child the more likely is the gland to suppurate.

6. Otitis Media and Mastoiditis.—Rarely is otitis media a cause of obscure fever if a thorough examination is made. However, from a practical standpoint it is often a cause of unexplained fever simply because the ear has not been properly examined. Save by those most expert an electrically lighted otoscope should be used. In cleaning the ear care should be taken that the drum itself is not injured, for then mild cases might be entirely overlooked or incorrectly diagnosed. In the young infant, crying produces some pinkness of the drum but the other signs will not indicate otitis.

The usual acute mastoiditis is obvious. Only in the so-called "hidden" types or when the infection extends into the petrous portion of the temporal bone rather than externally does the diagnosis and the cause of the fever become obscure. The so-called "hidden" mastoid is the type seen in young marantic infants. There is usually a discharging ear with no local signs over the mastoid area. A sagging of the posterior superior canal wall may be observed. Since some infection of the antrum is always seen in middle ear infections it is difficult to know what constitutes a definite so-called "mastoid (antrum) involvement." A posterior antrotomy performed on these patients often produces no change in the constitutional or febrile course of the patient.

In those cases where a petrous abscess develops the diagnosis is often obscure. Only when the abscess extends to the dural surface and produces a typical syndrome such as the "Gradenigo syndrome" is the diagnosis suspected.

However with this type of mastoid infection, as is usual in almost all mastoid infections, there is an associated otitis

media. Thus, when the temperature curve is at all out of the way for the simple case of otitis media, mastoid involvement should be suspected.

In those cases where an infected lymph node overlies the mastoid and where an otitis media exists it may prove very difficult to say whether or not mastoiditis exists. Such cases often require a period of observation before a conclusion can be reached.

FEVERS DUE TO LOWER RESPIRATORY INFECTIONS

CHARLES C. CHAPPLE

BEFORE considering lower respiratory infections it is well to have a few facts in mind. First, children under six years of age do not expectorate. When sputum is present it is swallowed or aspirated. Its absence from the bedside container does not mean its absence from the child. Second, the respiratory rate normally falls from 35 to 50 a minute in the newborn to 30 per minute for the remainder of the first year. After this period it gradually diminishes to 20 to 25 per minute for the rest of childhood and reaches the adult rate at puberty. With fever the respiratory rate is increased approximately $2\frac{1}{2}$ respirations per degree of elevation. A respiratory rate over 40 per minute warrants a tentative diagnosis of respiratory tract infection until it can be excluded.

Pneumonia.—Seldom indeed can pneumonia be safely discarded from the diagnostic possibilities in sudden, high fevers. Definite clinical evidence of its presence is frequently delayed and may not appear until the crisis. Abdominal pains and a rigid abdominal wall may be most misleading and extremely difficult of differentiation from an acute abdominal condition. x-Ray examination cannot be depended upon to give conclusive evidence against pneumonia's presence in the early stage of the disease. Fluoroscopy may be of value in the demonstration of limitation of diaphragmatic motion when an abdominal diagnosis must be ruled out. The white blood count tends to reach a much higher point in pneumonia than in acute abdominal disorders. But after all close clinical observation has no substitute as a diagnostic procedure.

Influenza.—The difficulty obtaining in the diagnosis of this disease is one of quite another order. This diagnosis is commonly used as a camouflage answer for all problems of obscure solution. A leukopenia of 6000 or below is a necessary concomitant of the fever, respiratory or gastro-intestinal signs when their cause is influenzal. Pfeiffer's bacillus can frequently be recovered from the throat and nose but is not at all diagnostic.

Diaphragmatic Pleurisy.—Signs on auscultation and percussion may be lacking in pleurisy especially when it is located exclusively on the diaphragm. Hiccough and abdominal pain may serve to fasten a diagnosis upon a pleuritic picture which offers no evidence to the stethoscope.

Encapsulated Empyema.—When a child fails to blossom after a pneumonia and the temperature persists though the chest sound clear, this condition is a first rank possibility. x-Ray plates will disclose the interlobar collection.

Multiple Lung Abscess.—When the individual abscesses are small, though they be myriad, there will be no sign demonstrable to auscultation or percussion. The clinical picture is one of great severity in other particulars. Chills, high fever, foul breath, cough, and expectoration are usual. Pallor, cyanosis, nausea, pleuritic pain and finger clubbing commonly accompany this condition. Dark-field examination of the sputum for spirochetes and fusiform bacilli should be performed. Smears and cultures of the expectorated matter must be examined for their presence. Roentgenograms will shortly give corroboration.

Bronchiectasis.—Fever recurs at irregular intervals in this condition but the x-ray plates of the chest, especially those taken after lipiodol injection, are diagnostic so that this disease can hardly be classified as of obscure origin.

Mediastinal Glands.—A persistent fever following an upper respiratory tract infection may be due to mediastinal gland involvement. Cough of a brassy type is frequently present here. The respiratory rate may be slower than that ex-

pected. Critical x-ray examination leads to the solution of this diagnostic problem.

Mediastinal Hodgkin's Disease.—Hodgkin's is described elsewhere.

Mediastinal Abscess.—A clue to the origin of this disturbance is usually to be found in the immediate past history of the child revealing a cervical or throat infection. The onset is one of great severity. Chills, high fever, and dyspnea are present. He sweats profusely and may complain of back-ache. A blood culture should be done immediately. The white blood count will be greatly elevated with a preponderance of polymorphonuclears. If the abscess be of appreciable size it will be demonstrable by x-ray.

Respiratory Tuberculosis.—Childhood tuberculosis presents quite a different picture from that seen in older persons. It is a primary disease in the child and secondary in the adult. This distinction is based upon the presence of tissue reactivity due to previous infection in the adult. It is analogous to, if not identical with, allergy. The child, receiving his first infection has not set up such responses of defense that he can confine the organisms to a small area. The primary site in the lung is the origin of lymphangitis between itself and the regional lymph nodes where a lymphadenitis is established. These three processes together are known as the primary triad. The adult walls off the organism at point of entry in the lung without the extensive lymphatic involvement characteristic of childhood tuberculosis. Childhood tuberculosis can occur in the adult who has had no previous exposure to the disease as can the adult type appear in the child with an earlier contact.

Once tuberculosis is established the symptoms and signs can be legion. Continuous low-grade fever, cough, night sweats, pallor, loss of appetite and secondary anemia are almost constantly present. The location of the tubercles determines the characteristics of other signs. These may be gastro-intestinal, genito-urinary, muscular, neurological, or

skeletal in type. Deafness, hoarseness, dimness of vision may be present. The variations are limitless.

x-Ray examination of the chest will reveal enlarged mediastinal glands and the primary site which is often found to be calcified. Old tuberculin injected intradermally will produce an area of redness at the point of inoculation in case either of present activity or past infection. The first skin test dose is $\frac{1}{100}$ mg. but this should be increased to 1 mg. if smaller doses be negative. A positive skin test is not to be understood as excluding all other causes of fever. Positive tests occur more and more frequently as the child grows older so that few adults have negative tests. The severity of the skin test reaction must be taken into consideration as well as all possible diagnostic means for the determination of other causes. It should be remembered that the skin test can be negative although tuberculosis be actively present. This is true after measles, for example, and in overwhelming miliary and meningitic forms of the disease.

FEVERS OF ABDOMINAL ORIGIN

JOHN MCKENNEY MITCHELL

CASES IN WHICH FEVER IS OF LONG DURATION AND VARIABLE DEGREE

ABDOMINAL tuberculosis must be granted a position of first importance in any search for the origin of fever in a child in whom the duration of such fever has been prolonged and where other symptoms may point even indefinitely to the abdomen. Tuberculous lesions of the intestines, peritoneum and mesenteric lymph nodes, although decreasing at a faster rate than those of the pulmonary region, remain a common site of tuberculosis in young children. They are found in a high percentage of autopsies on tuberculous children, in approximately 10 per cent of which they represent the oldest lesion.

Abdominal tuberculosis is most frequently primary, infection occurring through the intestines from infected food. A history of the habitual or periodic use of raw milk from untested or infrequently tested herds is obtainable in a large percentage of cases, and the incidence is decidedly lower in the cities than in rural and semirural areas where there is less rigid milk control and less pasteurization. Ice cream, "our own make," often from milk of uncertain origin is doubtless the source of others. A smaller number of cases are secondary to pulmonary tuberculosis, being derived from sputum which is coughed up and swallowed.

Intestinal tuberculosis presents symptoms of great irregularity. In the milder cases localizing manifestations are usually entirely absent, and the condition must be suspected

on the basis of the constitutional reaction, in which low-grade fever of unexplained origin is the most common factor. This may or may not be accompanied by loss of weight or failure to gain, anorexia, anemia, and fatigability. In the more advanced cases there is often diarrhea of an obstinate sort, and occult blood. Gross hemorrhages are not common.

Tuberculous peritonitis is associated with many of these advanced intestinal lesions in which case symptoms of low-grade peritoneal involvement are present. Abdominal pain and tenderness may however be absent. There is almost always some fever, 100° to 101° F., though even this may not develop early. A slowly developing ascites is the most common finding. In the plastic forms which develop more slowly and insidiously, fever is slight and often absent. As the condition advances fever appears and reaches higher levels. Tuberculous peritonitis may occur in cases in which intestinal tuberculosis is not discovered, it having been amply demonstrated that the infection may pass through the intestinal wall and leave no trace.

Cirrhosis of the liver is not infrequently confused with tuberculous peritonitis. Since this condition also often shows an evening rise of temperature, the presence of fever is of little diagnostic help.

In acute miliary tuberculosis blood-borne infection may leave tubercles scattered over the peritoneum and give no local signs. Fever is a prominent symptom.

Tuberculosis of the mesenteric lymph nodes is associated with tuberculosis of the intestines and peritoneum in the vast majority of instances and is frequently the only demonstrable lesion clinically or at autopsy. Such glands vary greatly in size, fusion sometimes resulting in palpable masses. They may be relatively symptomless but often produce fever, pain, local tenderness and rigidity, sometimes so great as to be confused with appendicitis. They are found somewhat more commonly (60 per cent) on the right side, and above McBurney's point, corresponding anatomically to the glands of the ileocecal mesentery. As active infection subsides and calcifica-

tion of the glands occurs, recurrent attacks of abdominal pain continue in about one half of the cases, in some instances over a period of years. In this stage fever is less apt to be present, usually only during the attacks of pain, and is of low grade (100° F.). Such glands are demonstrable roentgenologically and have been found to be present in from 1 to 2 per cent of abdominal plates of children between two and twelve years of age.

A positive tuberculin test is always present in abdominal tuberculosis and in the young child is the mainstay of the diagnosis. After calcification lesions of the mesenteric lymph nodes are readily demonstrable by flat x-ray plates of the abdomen and render possible a clear-cut diagnosis of this most common form, even when asymptomatic.

Rest, heliotherapy and attention to hygiene and diet with especial attention to removal of the source of infection when this is milk, are usually sufficient to eventually result in a cure. Surgical intervention with excision of involved glands should be reserved for those cases who fail to respond to symptomatic treatment.

CASES OF ACUTE FEBRILE ILLNESS IN WHICH FEVER IS A PREDOMINANT SYMPTOM AND SIGNS POINT ONLY INDEFINITELY TO THE ABDOMEN

Typhoid and Paratyphoid Fever.—Prominent among cases of this group are typhoid and paratyphoid fever. The onset is generally insidious but may be abrupt. In either event relatively high fever unexplained by any definite physical findings for some days is the rule. Fever reaches its height in from two to seven days, then fluctuates within the limits of 1 to 3 degrees for a variable period before subsiding gradually. Diagnostic signs are slow in appearing. The spleen is not palpable before the end of the first week, often later; rose spots which are far less constant in children than in adults may appear in the second week. It should be borne in mind that a mild leukocytosis is about as common as leukopenia, especially in the younger children. Constipation may be present

throughout the illness. Stool, blood and usually urine cultures are positive early, but the Widal reaction is not usually present until the tenth or even the twelfth day.

Bacillary dysentery is today a far more common disease among infants and children in this country than is typhoid. Fever is a prominent symptom, varying from slight elevations in mild cases to very high in severe ones. Vomiting, pain and diarrhea generally appear concomitantly with the fever but may be delayed for some hours, and the typical blood-streaked mucous stools may not appear for another day or even more. Blood is not usually present in great amount, but in the occasional case in which it does occur the differential diagnosis from intestinal obstruction is aided by the early appearance of fever in dysentery. Both conditions may show mucus free from feces, but that of intussusception contains very few cells while that of dysentery shows abundant polymorphonuclear cells.

The diagnosis of acute bacillary dysentery may be tentatively made when fever, toxemia, abdominal pain and tenderness are accompanied by diarrhea with bloody and mucous stools. Absolute diagnosis demands the recovery of the dysentery bacillus from the stool or positive agglutination tests (obtainable from the seventh to the fourteenth day after onset).

Amebic dysentery, rare in this country, is more gradual in onset. It is possible to demonstrate amebae in freshly passed stools kept warm. There are few cellular elements to be seen, polynuclear cells being rare among these. The blood shows a marked lymphocytic leukocytosis in contradistinction to the bacillary form where it is only slight and polynuclears are in the ascendency. In subacute and chronic cases recurrent attacks of fever and bloody mucous stools with pain and tenderness may alternate with periods of apparent recovery.

Ulcerative colitis shows many of the characteristics of bacillary dysentery in its later stages; but seldom produces high fever or considerable toxemia. Final differentiation must rest on stool cultures and agglutination tests.

CASES WITH AN ABRUPT ONSET AND SYMPTOMS POINTING TO AN ACUTE SURGICAL ABDOMEN

Acute surgical conditions involving the abdomen ordinarily have pain as their primary presenting symptom and the origin of fever is not long obscure. The presence or absence of fever is however frequently of diagnostic importance especially in those children who are too young to tell of their pain.

Acute Appendicitis.—The progressive appearance of pain, vomiting, localizing tenderness and then leukocytosis and fever is not apt to leave one long in doubt as to the cause of the latter. It is well to bear in mind, however, that even in an advanced appendicitis the temperature may not be above 100° or 101° F.

Chronic Appendicitis.—Fever is even less apt to be the cause of quandary in chronic appendicitis, mechanical factors gaining importance. Bouts of fever with the recurring attacks may however occur.

Peritonitis.—The frequency with which appendicitis in small children leads to perforation before operation, and is followed by peritonitis is too well known to need emphasis. In such cases the cause of fever is generally only too apparent. It is rather in the cases in which peritonitis develops as a primary infection or as an extension from some abscess more obscure than that of an appendix, that fever may be of undetermined origin for a variable period.

Primary pneumococcus or streptococcus peritonitis is usually abrupt in onset with fever and vomiting. The temperature is generally high, 103° to 105° F. Older children will complain of pain and the abdomen is soon distended and tympanic. Rigidity may be marked but in the younger children this sign cannot be depended upon. The condition occurs most frequently in girls and is thought sometimes to have its origin in vaginal infection.

The possibility of pneumococcus or streptococcus peritonitis must be borne in mind when a patient with nephrosis develops fever of otherwise unexplained origin, accompanied or followed by vomiting, pain, leukocytosis and other though

vague localizing signs. The appearance of this condition in the course of nephrosis or of nephritis with a nephrotic syndrome is not rare or casual.

Abscesses in the abdominal region may long remain the cause of fever of unknown origin, then finally rupture into the peritoneum and excite peritonitis. In children the most frequent of these abscesses are associated with Pott's disease, perinephritis and cellulitis of the abdominal wall. Peritonitis occasionally follows infection of the female genital tract, even from a gonococcus vaginitis. It may result from extension of a pleural empyema through the diaphragm. The symptoms and signs are those of empyema and differentiation will usually only be made by *x-ray*.

Subphrenic abscesses may also have their origin in *abscesses of the liver*. These are very rare, occasionally occurring secondary to suppurative pylephlebitis from infection of the umbilical vein. Seven of 34 cases collected by Musser were due to migration of round-worms into the hepatic ducts. Fever is a prominent symptom and usually of the hectic type. It is accompanied by chills and followed by sweating, prostration, vomiting and diarrhea. Jaundice is only irregularly present. The liver is generally enlarged and tender. Aspiration of "liver pus" represents the only positive diagnosis. Duration from the beginning of symptoms is usually one to two months. Prognosis is poor, treatment is surgical unless the abscess is secondary to amebic colitis.

Acute pancreatitis is very rare. The main symptoms are epigastric pain, vomiting, constipation, fever. It stimulates acute intestinal obstruction and acute peritonitis. Diagnosis is generally made only after laparotomy.

CASES OF FEVER OF OBSCURE ORIGIN IN WHICH THE SYMPTOMS SIMULATE THOSE OF AN ACUTE ABDOMEN

A syndrome rarely discussed in texts and journals though so common in the experience of every practitioner among children, is that which, for want of a better name has been called "**intestinal gripe**." Fever, vomiting, abdominal pain

and diarrhea occurring in any possible combination and varying in type and severity in different epidemics, may so closely simulate appendicitis as to render diagnosis difficult. Many of these cases show a leukopenia which is helpful in differentiation. As indicated, fever may occur alone, in which cases explanation of its origin may be impossible except on the basis of the presence of the disease in epidemic numbers. The condition is usually of short duration and only moderate severity except in the occasional case in which the vomiting becomes persistent and attendant symptoms develop due to this fact. The causative organism has not been determined.

Fever may be the sole finding in the early stages of **acute rheumatic fever**. Before carditis or joint manifestations are demonstrable, abdominal pain so severe as to be confused with appendicitis occasionally occurs. Such cases have at times come to operation, revealing diffuse congestion of the peritoneum without evidence of pyogenic infection. The same is true of acute infections of the upper urinary tract, or non-tuberculous mesenteric adenitis and in the course of septic sore throat.

Food Poisoning.—How frequently the physician must fall back on the diagnosis of "food poisoning," "acute indigestion," "gastro-enteritis," "digestive upset," "ptomaine poisoning" and the like, will be known only to himself. In what percentage of cases the symptoms of diarrhea and fever, usually accompanied by nausea, vomiting and abdominal pain are unjustly attributed to bacterial food infection will depend upon the care and honesty with which the individual makes his diagnoses.

Such infections are caused by bacteria of the paratyphoid-enteritidis group which includes *Bacillus paratyphosus* alpha and beta, *B. enteritidis*, *B. suipestifer* (a secondary invader in hog cholera) and *B. aertrycke* (a name applied to *B. suipestifer* of human origin). Onset is usually sudden, occurring in from six to twelve hours after the infected food is eaten. In some instances symptoms appear so quickly after its ingestion that some investigators incline to the view

that a toxin preformed in the food by the bacteria is responsible. (The term "ptomaine poisoning" should not be used in such cases however and should be entirely eliminated from medical nomenclature.) There is the widest discrepancy in the severity of symptoms in different outbreaks and in individuals in a given outbreak. They vary all the way from general malaise and nausea without fever, to prostration and shock eventuating in death.

Fever is present in a typical case; in one of moderate severity beginning soon after the onset of gastro-intestinal disturbance and rising rapidly to 102° to 104° F.

Ordinarily in institutional and other group outbreaks diagnosis is not difficult. Children, however, are more susceptible than adults and not infrequently a child alone in a household may be affected. With the rapidity of developments in appendicitis in mind, the physician will be faced with the necessity of early decision. It is here that the fever becomes of diagnostic importance. In food poisoning the temperature is higher in proportion to the amount of pain than in appendicitis.

Occasionally, after a typical acute onset the fever may persist for weeks. This is most frequently the case when *B. paratyphosus* is the infecting organism. We have recently seen, however, several cases in which long spells of irregular fever accompanied by normal stools have finally been explained by the finding of *B. aertrycke* or *B. suipestifer* in the stools. The importance of making stool cultures is emphasized by these cases.

Outbreaks of "food poisoning" after banquets have been traced to the use of eating utensils to which silver polish had recently been applied and insufficiently removed by washing.

Botulism is caused by a true bacterial toxin produced by the *Bacillus botulinus* and found most frequently in home-canned vegetables, fruits, and meats. In about one third of the cases there is initial nausea, vomiting, diarrhea, abdominal pain and fever which develop a few hours after the ingestion of the food and are probably caused by local irritation of the gastro-intestinal tract by the spoiled material. These symp-

toms generally cease as soon as the typical symptoms of intoxication develop some twenty-four to forty-eight hours later. The typical case of botulism is characterized by disturbance of vision, difficulty in talking and swallowing, persistent constipation, marked muscular weakness, absence of sensory disturbance, subnormal temperature and rapid pulse.

The condition is included here largely because in 2 of 3 proved cases in children recently seen by one of us, it was impossible to demonstrate any of the above described symptoms; they had a profuse and prolonged diarrhea and fever of 100° to 101° F. for some days. In the third case, which was fatal, prostration was so great from the time of onset of symptoms to death forty-eight hours later that aside from the extreme weakness it was possible only to demonstrate dilated and relatively fixed pupils. This patient had high fever for at least twenty-four hours before death and no intercurrent infection was found at autopsy to account for it.

Epidemic jaundice starts with symptoms no more definite than low-grade fever, lassitude, irritability and anorexia. It may prove extremely difficult to elucidate the cause of the fever until jaundice appears, which is usually on the third or fourth day but may be delayed even as late as the twelfth day. Next to jaundice, fever, which may reach 104° F., is the most constant symptom. Abdominal pain localized in the right upper quadrant is a common complaint. The disease occurs most commonly in children and young adults in institutional epidemics which simplifies diagnosis, but sporadic cases do occur.

The causative organism has generally been considered undetermined, the condition being distinguished from *Weil's disease* by its lesser severity, absence of hemorrhages in the skin and mucous membranes, absence of hematuria and repeated failures to obtain *Leptospira icterohemorrhagiae* from individuals with the disease. In a recently reported epidemic in a religious school, however, this organism was recovered repeatedly from the holy water fonts though not from the patients. This might be considered to lend some additional credence to the view that an attenuated form of this organism is the cause of epidemic jaundice.

FEVERS DUE TO DISEASES OF THE URINARY TRACT

MITCHELL I. RUBIN

THE urinary tract is notorious for its ability and frequency in harboring the cause of obscure fever. Not infrequently, however, it is unjustly incriminated. Clinicians have so often been misled in the early diagnosis of pyogenic disease of the kidney that it has now become just another case of "The Boy Who Cried Wolf." The most important single sign of infection in the urinary tract is pyuria. Since this one sign is of such diagnostic importance it seems wise to discuss the significance of pus in the urine *per se*.

1. **Pyuria ("Pyelitis").**—The freshly passed urine is best examined after thorough shaking, placing a drop under a coverslip. Normally in boys the uncentrifuged urine contains 2 to 3 leukocytes per low-power field (20 to 30 per cubic millimeter), while for girls the normal number of leukocytes is from 6 to 8 (60 to 80 per cubic millimeter). In a study of the urinary cell count in a large series of febrile children after tonsillectomy, carried on at the Children's Memorial Hospital in Chicago, a sharp increase in the number of leukocytes was found. This increase of cells returned to normal when the temperature subsided. In these cases no evidence of urinary tract infection was demonstrable. Often in other febrile disturbances there is an increase in the urinary cell count which returns to normal with a subsidence of the fever. In girls the commonest cause of pyuria is vaginitis.

Not every specimen in a case of so-called "pyelitis" (pyuria) shows an increased number of pus cells; often there are none at all at the beginning of the disease. For this

reason several examinations over a period of many days are necessary. The fever usually shows an inverse relationship to the quantity of pus in the urine, the pus often appearing only when the temperature has fallen to normal. There are cases where infection of the urinary tract is only demonstrable by the presence of a colon bacillus bacilluria, for that reason urine cultures should be made before a patient with a urinary infection is discharged as cured.

The commonest instances where the urinary tract is the cause of obscure fever are cases of so-called "pyelitis." From pathological studies it seems that those instances where the pathology is limited to the pelvis of the kidney must be uncommon. At autopsy infection in the kidney substance as well is most often found. However, it is to be remembered that the mild cases do not succumb. In this disease the fever is usually high and fluctuating for two to three days, then subsides gradually or falls by crisis. The association of this type of fever with chills in children should suggest the possibility of pyelitis. In infants collapse attacks might replace the chills, as is seen in malaria. Abdominal discomfort, urinary frequency and dysuria are frequently associated. Rarely does muscle spasm and pain over the kidney region denote pyelitis. When these are present infection in the perinephric space or the kidney parenchyma itself should be suspected. Often there are symptoms involving the gastro-intestinal tract and central nervous system during the attack. Febrile attacks of pyelitis frequently recur. Between the attacks the urine may be free of pus, the only evidence of infection being bacilluria. The patient can only be considered cured when the urine is sterile.

Low-grade fever in chronic urinary infection may persist for weeks or months. When it is associated with continued pyuria, a congenital malformation of the urinary tract with secondary infection must be considered. It has been our custom to study the patient for the possibility of urinary tract malformation if pyuria persists for two months after adequate medical care. There are few symptoms save those of obstruc-

tion to the passage of urine or late signs of kidney insufficiency in cases of congenital urinary malformation when infection is not present. At times the patients go for years before infection takes place. In most cases the instillation of a sodium iodide solution into the bladder will demonstrate by means of the x-ray when the patient's buttocks are elevated, a reflux into abnormally dilated ureters and kidney pelves. The valve type of posterior urethral obstruction allows the catheter easily to enter the bladder but prevents the passage of the urine from the bladder out into the urethra.

2. **Carbuncle or multiple abscesses of the kidney** are usually associated with obvious infection elsewhere, usually in the upper respiratory tract. Often, however, when the patient first comes under observation, the respiratory infection has cleared and the cause for the fever has now become obscure. The urine in many of these cases is free of pus. When pyuria is present along with the local signs of kidney involvement such as pain and tenderness, the diagnosis is not obscure. In all cases of unexplained fever the urinary tract should be suspected. Since septicemia is so often present in these cases of severe kidney infections the temperature is typically septic. The infecting organism here is usually the hemolytic streptococcus or staphylococcus. The blood shows a marked polymorphonuclear leukocytosis.

3. **Perinephric abscess** is not a rare cause of obscure fever and like osteomyelitis is often not diagnosed simply because it is not considered among the possibilities. The majority of cases are undiagnosed until the abscess fills the flank and there are local signs of abscess. Since in about one half the cases pyuria is not present, the kidney region is not suspected as the cause for the fever. In routine examination the kidney region is too often overlooked; this probably accounts for the many instances where the diagnosis is not made. The type of fever here is that of sepsis, fluctuating widely, and chills may be present. One of the characteristic signs is flexion of the leg on the involved side due to psoas muscle spasm resulting from irritation by the abscess. The origin of peri-

nephric abscess is embolic, often the abscess results from the rupture of an abscess in the kidney cortex into the perinephric fat.

4. **Tuberculosis of the kidney** as a cause of obscure fever is rare in early life. When the kidney involvement is a part of a generalized tuberculosis, as it usually is, there often are no characteristic symptoms. When the lesion in the kidney is the major one, pain and tenderness in the kidney region with pus and blood cells in the urine help to make the diagnosis. A positive tuberculin skin reaction and x-ray studies of the chest further aid in arriving at the cause for the fever. The presence of tubercle bacilli in the urine clinch the diagnosis. Bladder symptoms are much less common in children than in adults with this disease.

5. **Cystitis** alone is unusual in children. Because of the local symptoms, dysuria, frequency, pain, and the finding of pus in the urine, cystitis is rarely a cause of obscure fever.

6. **Urinary calculi**, because of their characteristic symptoms, pain, pyuria, and hematuria, are not a common cause of obscure fever.

7. **Neoplasms** of the urinary tract save for those in the kidney are very rare in childhood. Those of the kidney are uncommon and usually produce no fever until late in the disease. When the patient is admitted to the hospital with such a tumor, the disease is usually well advanced. The first symptom that seems to attract the mother's attention is an abdominal mass. By this time the disease has progressed in most instances beyond repair. When these patients are brought to the hospital fever is usually well established and continues on until death. The temperature curve is of the septic type but the fluctuations are less pronounced. The blood may show only a slight leukocytosis. The urine contains albumin, red blood cells, and leukocytes. On physical examination aside from the cachexia the abdominal tumor is the only finding. Rarely does true metastasis occur, the tumor spreading by direct extension.

FEVERS DISCUSSED FROM THE STANDPOINT OF CENTRAL NERVOUS SYSTEM DISEASE

T. S. WILDER

THE symptom of fever (without signs which point to an organic cause) is often the sole warning of an infectious or other lesion of the central nervous system. Sooner or later localizing signs and symptoms will usually develop, *provided one waits for them*. If too much time is lost, however, in making a diagnosis, the chances of effective treatment are materially diminished. One may say, of course, and rightly, that this is true of all obscure febrile states. Yet disease of the brain and its coverings carries graver implications, and in dealing with it delay is perhaps just a bit more serious, than is the case with the generality of disease involving other parts of the body.

The mere presence of fever suggests infection, and in most instances infection will prove to be the responsible agent. We shall therefore consider it first, taking up later the more remote causes of hyperpyrexia wherein an invading organism is not involved.

Infections of the central nervous system, by and large, can be counted upon to furnish us with signs which direct our attention to that particular part of the body. It is unnecessary to review the wide variety of neurological effects which one may encounter, since we are not dealing, here, with the conventional manifestations of these diseases, but rather with the exceptional, atypical, phenomena.

1. **Meningococcic Meningitis.**—Among the different types of meningitis perhaps this one most frequently fails to furnish us with classical signs during the first week or two

after its onset. One reason for this may be the fact that there is considerable variation in the pathogenicity of various strains of the meningococcus.

Hence, one sees now and then a child with moderately high fever, and general symptoms of mild toxicity, who does not exhibit stiffness of the back or neck, exaggeration of the reflexes, convulsions, or any other signs of neurological disturbance. And yet, after a varying amount of delay, one discovers the patient has meningitis. The following 4 cases, from four different hospitals, may serve as illustrations.

(a) A female infant, eight months old, was brought to the hospital with the complaint of diarrhea, and a temperature of around 104° F. The respirations were quite rapid, and the admission diagnosis was tentatively that of primary pneumonia. There were no obvious signs pointing to the central nervous system. The stools proved indeed to be frequent and loose. The expected pneumonia did not materialize. This infant, however, had a "cephalic" type of cry, a high white count, and after the lapse of a few days lumbar puncture was performed on those slender indications. There was marked pleocytosis, with meningococci present, and following a short course of treatment the infant recovered completely.

(b) Another child, aged three years, was brought to the hospital with fever, moderate toxicity, and complete absence of signs pointing toward a cause. The child was observed for eight or nine days, during which time the usual laboratory procedures were carried out. Finally, purely to rule out a central nervous system infection, lumbar puncture was done, and pleocytosis with meningococci established the correct diagnosis.

In this child, likewise, a minimum of treatment effected complete cure, suggesting that the infection was due to a strain of low virulence.

(c) A girl of four years was admitted to the hospital with a temperature fluctuating between 103° and 105° F. Again physical examination was essentially negative, except for signs referable to a moderately severe generalized infection. Three or four days after admission it was noted that a macular erup-

tion was present on the trunk and abdomen. Remembering that meningococcic meningitis is often called "spotted fever," a lumbar puncture was done, and this, of course, immediately revealed the true nature of the disease.

(d) A boy of ten months was admitted to the hospital with hyperpyrexia and some evidence of cerebral irritation. On the following day a rash appeared, which involved the whole body and face, and in fact, suggested the eruption of measles, more than anything else. But of course, other signs of measles were lacking. Lumbar puncture was done immediately, and demonstrated the presence of meningococcic meningitis, secondary, as in the preceding patient, of course, to meningococcic septicemia.

In a sense it is perhaps incorrect to refer to cases like the above as examples of fever of undetermined origin. Practically, however, they illustrate the frequency with which meningococcic meningitis fails to furnish clues as to its presence. Cases such as these justify us in attaching weight to slight indications for lumbar puncture, such as a cry, possibly cerebral, or a rash suggestive of that which sometimes accompanies this particular infection.

2. Tuberculous Meningitis.—This highly fatal infection is notorious, perhaps, for the inconstancy of its symptoms and signs. These vary, both in different patients, and at various times in the same patient. Usually, however, neurological symptoms of one sort or another are present. Whereas neck and spine may be of normal flexibility, one patient may have developed a strabismus or nystagmus. Another may show transitory weakness of certain muscle groups. In still another there may be bulging of the fontanel, and vomiting, suggestive of increased intracranial pressure. A certain proportion of cases, however, will at first show few signs other than severe toxicity, and possibly stupor. The temperature may be very slightly elevated, that is from 100° to 101° F., or it may be much higher, and there may be such general symptoms as anorexia, loss of weight, diarrhea, dehydration, etc. Usually the infant or child exhibits marked prostration and list-

lessness, which in themselves may suggest to one the possibility of tuberculous meningitis. In such situations, of course, lumbar puncture is "de rigueur," irrespective of whether the tuberculin test is positive or negative.

3. Meningitis Due to Streptococcus, Staphylococcus, Pneumococcus, Pfeiffer's Bacillus, Colon Bacillus, and Other Common Organisms.—In general, it may be stated that meningitis due to these particular pathogens runs a more fulminating course than the two previously mentioned types, and that the characteristic signs and symptoms are therefore almost invariably present. Marked rigidity of the neck, marked opisthotonus, and frequently convulsions are to be expected, so that one is rarely long in doubt as to the situation. Here again, however, the patient occasionally may be met whose signs of meningitis are submerged under the toxicity of an already existing acute infection to which the meningitis is secondary. In such instances lumbar puncture is called for, if only to clarify the situation and assist in prognosis.

In this group also may be included certain rare forms of meningitis such as that caused by the lactic acid bacillus, and that caused by any one of various strains of organisms which may be classed as "molds." These infections usually develop out of a clear sky, and exhibit the same signs as the more usual types of meningitis. Whereas the prognosis may not be as hopeless as in the case of streptococcus or staphylococcus infections the difference is not great.

4. Poliomyelitis.—With this disease an early diagnosis is desirable from the public health viewpoint, regardless of the fact that its achievement does not materially affect the outcome. During an epidemic, when, so to speak, infantile paralysis is "in the air," preparalytic diagnoses are not hard to make.

The sporadic, isolated case, however, may present definite difficulties, one of the principal ones being failure on the part of the diagnostician to keep this disease in mind at all times. The second difficulty lies in the fact that poliomyelitis usually causes much less striking neurological signs than does menin-

gitis proper. There is usually no real rigidity of the neck but rather only a slightly increased resistance to flexion. The stiffness of the back is somewhat more marked, but this sign too may be almost wanting. Other neurological signs such as tremor, paresthesia, hyperactive reflexes, cerebral tache, and so forth, may or may not be present.

Certainly it is not uncommon for paralysis to develop in the absence of fever or discomfort of any kind. Lumbar puncture, when in doubt, will often clinch the diagnosis, but even this procedure does not always serve to distinguish poliomyelitis from luetic meningitis, encephalitis, or the so-called "lymphocytic chorio-meningo-encephalitis" (until paralysis has developed!). Such exceptions, however, do not alter the fact that careful examination and summation of the variety of signs and symptoms will usually enable one to diagnose this disease in the preparalytic stage, if one keeps it in mind.

5. **Encephalitis** deserves inclusion in the group under discussion because of the variability of symptoms at the onset, and the fact that signs of meningeal irritation may be wanting. This applies both to so-called "epidemic encephalitis," and to those supposed instances of the disease which may be the same thing but no doubt are often called encephalitis for lack of a better name. Usually there is no cervical rigidity nor a positive Kernig sign; the fever, headache, and drowsiness might accompany almost any acute infection. Hence encephalitis is a condition which at times offers obstacles to diagnosis, and should therefore be kept all the more in mind. It would appear that this disease is on the increase, also that differing strains of the virus supposed to be responsible are coming to light. This last fact accounts for the marked variations in the clinical course of the disease in different parts of the country.

The onset may be acute, or there may be a moderate fever for some time before a definite diagnosis can be achieved. Eventually, however, suggestive signs begin to show themselves, such as diplopia, ptosis of the lids, coma, convulsions, and weaknesses of the eye and other muscles. There may even

be sufficient stimulation of the respiratory rate to produce a "forced breathing" alkalosis.

A lumbar puncture will usually help in diagnosis, the spinal fluid showing a definite though slight pleocytosis in most cases. Usually the cells are entirely of the mononuclear type, and aside from a slight increase in the globulin the spinal fluid is otherwise normal.

While considering encephalitis in general, possibly mention should be made of the special situations in which it may occur following acute infections such as measles, mumps, chickenpox, pertussis, and so forth. If during the convalescence from any one of these diseases the temperature becomes elevated, the possibility of a complicating encephalitis should be kept in mind, particularly if there are the slightest concomitant signs pointing toward the central nervous system.

In this type of encephalitis, to be sure, there is more apt to be evidence of meningeal irritation, and the number of cells in the spinal fluid is usually greater than in the epidemic types. The severity seems to depend somewhat upon the preceding diseases, the mortality following varicella and pertussis being high, and that following measles and mumps being low.

6. Acute Lymphocytic Meningitis.—This disease entity, if such it be, has attracted considerable attention during the last two or three years. In certain respects it resembles epidemic encephalitis; in other ways suggests poliomyelitis.

Following vague prodromal symptoms of upper respiratory infection there is an acute onset of headache, malaise, fever, vomiting, and slight stiffness of the neck. The Kernig sign may be slightly positive.

Cranial nerve involvement is very much less common than, for instance, in epidemic encephalitis. Usually there is no choking of the disks, except perhaps in protracted cases.

The outstanding feature of this disease, and the one which furnishes its name is, of course, marked pleocytosis (lymphocytic) of the spinal fluid. The cell count is much higher than it is in epidemic encephalitis, or in poliomyelitis, yet the white blood count is scarcely above normal.

That this disease is due to a virus is indicated, for example, by the work of Rivers and Scott, who have reported two human cases, together with the characteristics of the infection induced in mice and guinea-pigs by intracerebral inoculation. (T. F. McNair Scott and Thomas M. Rivers, *Jour. Exp. Med.*, 63, pp. 397 and 415, March, 1936.) They have likewise shown, with the aid of Armstrong and Lillie, and of Traub, that the Rivers-Scott virus is identical immunologically with the virus independently studied by those investigators. The infection may occur in mice and guinea-pigs and monkeys, as well as in man, but appears not to be highly contagious.

6a. **Acute Aseptic Meningitis.**—This term was coined by Wallgren, in 1925. (A. Wallgren, *Acta pediat.*, 1925, 4, p. 158.) It may be applied to those types of meningitis occasionally encountered, which cause pleocytosis of the spinal fluid (mainly mononuclear) without demonstrable organisms. Naturally the term covers a wide field, including the above-mentioned acute lymphocytic meningitis. Evidence at hand indeed indicates that there are a number of different viruses which may be responsible for much the same clinical picture. For instance, Rivers and Scott have shown that the serum of many patients convalescing from "acute aseptic meningitis" does not inactivate their virus. A recent instance of this is an epidemic which occurred in Philadelphia during the fall of 1935. The syndrome was one of severe headache, photophobia, occasional convulsions, a good prognosis, and freedom from sequelae. Yet this so-called "Philadelphia headache disease" has already been shown by Rivers and Scott to differ immunologically from their "acute lymphocytic meningitis." Certainly hundreds of cases must have occurred, when one considers the fact that a series of 45 was reported by one hospital, and that all other hospitals with which we are acquainted cared for a number of patients with what appeared to be the same disease.

Practitioners, however, soon came to regard the syndrome rather lightly, owing to the fact that nearly all cases ran a rapid course without apparent sequelae. And yet in any individual patient the symptoms were severe enough at the onset

to be alarming, particularly since diagnosis was not at first apparent. Occurring in children of all ages (less frequently in adults), the onset with slight or moderate fever suggested a central nervous disturbance, yet such signs as rigidity of neck and back, positive Kernig, etc., were usually indefinite, or lacking. In some patients the reflexes were hyperactive, but in others appeared to be either diminished, or normal. Subjective symptoms were definitely more striking, although there again considerable variation was observed. Most patients, for instance, complained chiefly of headache, some of vertigo, others of pain in the eyes, and others of marked disturbance in vision, even to the point of temporary blindness. Although spinal fluid findings suggested poliomyelitis, convulsions were far more frequent than in that disease. Moreover, the minor signs and symptoms, taken as a whole, were decidedly different.

The mortality was practically nil, and no cases were followed by paralysis of any sort. It has been said that this condition represents a new disease, but others feel that we have had it with us for years, and that in the past it has been confused with abortive poliomyelitis. It is highly probable that the involuntary statistical inclusion of syndromes of this sort in the mortality records of various outbreaks of poliomyelitis explains the curiously wide fluctuations in death rate characteristic of the latter disease. Indeed, it would be difficult to prove that the two were separate clinical entities unless, as occurred in Philadelphia, numerous cases of the former were seen during a short period of time without manifesting any of the expected sequelae of infantile paralysis, and in the absence of an epidemic of the latter.

With increasing recognition of this and allied conditions, more certain differentiation between them and poliomyelitis will no doubt be possible. Progress must necessarily be slow, however, owing to the notorious difficulties inherent in the study of virus diseases.

7. Syphilitic Meningitis.—Occasionally meningo-vascular syphilis may be responsible for fever and other evidences of acute infection without striking neurological signs. Of

course, a history of syphilis will be helpful, and a Wassermann test on the spinal fluid will usually establish the correct diagnosis. In this connection it should be remembered, however, that a patient whose blood Wassermann is negative may have a positive spinal fluid. Indeed, Wm. C. Menninger and Leon Bromberg (Jour. Lab. and Clin. Med., vol. 20, p. 628, April, 1935) state that 31 per cent of a group of 500 cases of neurosyphilis had a negative blood Wassermann test. Hence, when one gets as far as the spinal fluid in a case of undiagnosed hyperpyrexia, and when the cytology is suggestive, a Wassermann or equivalent test should by all means be performed. There will be times when this test is absolutely necessary in differentiating between central nervous system lues and such conditions as poliomyelitis, encephalitis, and tuberculous meningitis.

8. **Brain Abscess.**—Often one of the most obscure intracranial lesions, from the standpoint of diagnosis, is that of *chronic cerebral abscess*. As everyone knows, symptoms may be almost entirely lacking. (Of acute fulminating brain abscess, such as may follow infections of the mastoid or accessory sinuses, this is of course not true.)

A chronic brain abscess may be entirely asymptomatic aside from a slight afternoon rise in temperature, headache, and perhaps some leukocytosis. (Indeed, even these signs may be absent.) At this stage, of course, no one could be blamed for failing to undertake the rather complicated procedures which might lead to a diagnosis. However, one can at least keep the possibility in mind, and can watch carefully for symptoms of pressure, and for the first localizing signs that may appear. One will then be ready to resort to lumbar puncture, ventriculogram, or to neurosurgical consultation as soon as indications arise.

9. **Pachymeningitis**, although rare, deserves mention, since it too may cause a slight elevation of temperature, and since it is one of those conditions which more often than not, perhaps, is first diagnosed at autopsy. In the later stages, of course, pachymeningitis may be suspected on the basis of

increasing malaise, fretfulness, and progressive enlargement of the head. Ophthalmic examination will then probably reveal retinal hemorrhages, and insertion of a needle into the subdural space will often disclose xanthochromic or hemorrhagic fluid. Certainly, however, the disease becomes far advanced, in many cases, before one can suspect its presence.

10. **Other infections**, involving the central nervous system could be listed ad nauseam, but they need not be mentioned here, because of rarity, or because in some instances they even lack a name. Suffice it to say that atypical manifestations of infection are always turning up, and that from time to time even a new clinical entity is described.

The fact that occasionally a patient is seen with central nervous involvement of a sort which can hardly be classified is illustrated by the following case notes:

A ten-month female infant was admitted to the hospital with an upper respiratory infection, and a high temperature. During the course of six weeks the fever gradually subsided, and the spinal fluid which showed originally 134 cells, largely mononuclear, continued for nearly six months to have an abnormally high, though diminishing number of cells. The child improved slowly, and eventually appeared to have recovered completely. Diseases such as typhoid, syphilis, meningococcic meningitis, etc., were ruled out, and cultures of the spinal fluid were at all times negative. No organisms were discovered on any occasion. The tuberculin test was mildly positive, and the diagnosis lay perhaps between tuberculoma and a low-grade brain abscess. No definite decision was made regarding the cause of the abnormal signs, and at no time were there any indications pointing to localization of a lesion in the central nervous system. Conceivably this patient may come down with tuberculous meningitis in the future, or may develop evidences of infection somewhere in the brain.

Thus far we have discussed only causes of an infectious nature for obscure hyperpyrexia originating in the central nervous system.

Infection, naturally, is most frequently proved responsible,

but, occasionally one has to consider other possibilities. These divide themselves roughly into 3 groups: *first, mechanical lesions* acting upon the heat regulatory mechanism of the central nervous system, *second, toxins or drugs* which also affect that portion of the brain, and *third, disease* which does likewise.

11. **Mechanical factors** are of such great variety that we cannot here attempt a listing of them. In brief, any trauma which injures or causes hemorrhage in the midbrain may produce hyperpyrexia, which sometimes persists for a long time after the acute effect of the lesion has subsided. To prove this point is often difficult, and to influence the natural course of the process is hardly to be hoped for.

12. **Toxic substances** or drugs may cause fever by acting partly, no doubt, on the midbrain, though usually the most obvious lesions as reported at autopsy are more generalized, and consist in widespread hemorrhagic "encephalitis" (so called) together with myelitis. This may occur, for instance, following intravenous arsphenamine. The symptoms as reported by M. A. Glaser, C. P. Imerman, and S. W. Imerman (Amer. Jour. Med. Sci., vol. 189, p. 64, January 9, 1935), consist of headache, vomiting, nervousness, dizziness, cyanosis, and hyperpyrexia. To be sure, the course is usually fulminating and the history does suggest the cause; but that an actual hemorrhagic encephalopathy can occur under these conditions is worth bearing in mind.

Other drugs known to cause similar effects include salicylates, of which methyl salicylate is perhaps the most toxic, so far as the cerebral cortex is concerned. Lead, also, under certain circumstances may cause fever as an effect of the encephalopathy for which it is responsible. The prognosis, once a diagnosis has been made, is grave, but depends in part on the severity of the intoxication, and in part on the sensitivity or susceptibility of the individual, since a fatal outcome may result from comparatively small amounts of the drug or poison. It should not be forgotten that still other drugs, with a more general effect can likewise cause fever, examples being, atropine, phenobarbital, nirvanol, etc.

13. Disease affecting the central nervous system in such a manner as to produce obscure fever groups itself according to its local effect rather than according to its nature. Thus we have a wide variation from which to pick a few examples. For instance, it sounds somewhat far fetched to say that if a child will not take his orange juice he may end up with a "stroke," and die with a temperature of 108° or 109° F., but such cases are by no means rare. As a matter of fact, when a child admitted to the hospital with scurvy develops a fever not accounted for by any other condition, one should consider carefully the possibility of intracranial hemorrhage, and too often may find at autopsy that the thing can readily occur.

Similarly any anomaly such as an aneurysm or an arterio-venous fistula, or any weakness of the vessel walls or thrombus, which may result in hemorrhage in the midbrain area, can produce hyperpyrexia.

To these also may be added blood dyscrasias such as purpuras, leukemias, hemophilia, in short anything which may, under rare circumstances, cause bleeding in the vital portion of the brain.

Finally, although brain tumor is not often the cause of fever, the exceptional case may be encountered where hyperpyrexia is an early and persistent symptom. As an extreme example Cornelia de Lange (*Acta Pediat.*, July, 1933, quoted in the 1933 Year Book of Pediatrics) reports the case of a child who exhibited a fever of six and one-half years' duration, with only occasional days of remission. The evening temperature was higher than the morning, usually reaching 102° F., by rectum. Signs and symptoms were chiefly those of progressive weakness accompanied by pain. There was profuse perspiration, and muscle atrophy developed. Autopsy revealed, among other things, a tumor in the medulla, together with a spindle-shaped enlargement of the thoracic cord. This tumor, the author believes, interfered with inhibitory impulses of the heat-regulating fibers passing through the cervical cord.

FEVERS DUE TO MISCELLANEOUS CONDITIONS

CHARLES C. CHAPPLE

It would appear advisable to give a short summary of the usual clinical picture of each disease which can present fever of obscure origin as one of its features. To discuss the ramifications and variations of each is neither possible nor justifiable here.

Dehydration Fever.—This fever is common in the newborn before the mother's milk has become sufficient and while the child is on a low fluid intake. At this time the condition is a true clinical entity. Later in infancy dehydration must be considered at all times as an added factor in the etiology of temperature elevations. These babies have skin which lacks elasticity and feels dry to the touch. The most rational means of diagnosis is likewise the most rational method of treatment. Supplying fluid by mouth, subcutaneously or through any of the other routes brings an immediate drop in the fever and a loss of the skin signs. Should the question of diagnosis appear more complex it is possible to be absolutely definite by laboratory procedures. The blood urea and chlorides are routinely increased and the serum calcium, as well as the volume percentage of oxygen capacity, is above normal limits.

Sepsis of the Newborn.—Fever is expected in this disease though occasionally it fails to appear. Protracted and severe jaundice is the common finding of significance. Loss of weight, pallor, and increased sweating closely follow the jaundice in frequency of occurrence. Other signs are more variable in their appearance. Nausea and vomiting or diar-

rhea may be present. Petechiae seldom fail to be visible but their arrival may be delayed.

One should look first for a possible etiological source. An infected umbilicus or an apparently mild impetigo may be the focus. Rarely, none can be located. A blood culture should be done at once to establish the diagnosis. The white blood cell count gives evidence of severe infection.

Mechanical Prevention of Evaporation.—Prematures are notoriously thermolabile. To a somewhat less degree children with fevers are also thermolabile. In these two groups especially, blankets, heating cradles, and even casts may become important producers of hyperpyrexia. Post-anesthesia technic requires that the child be kept warm. If the same routine be followed by nurses the year round the incidence of high fever will be much greater during the summer months. Common sense can keep the number of blankets seasonal and reasonable.

Teething.—In the thermolabile infant teething can be the cause of high fever. The tendency is to attribute far more symptoms and signs to the teeth than they cause. However, when all other possibilities are eliminated the gums must be considered. Commonly they are swollen and reddened when they are the source of discomfort and fever. Occasionally they appear to be innocuous but the constant chewing and biting of the infant puts them under suspicion.

Abscessed Teeth.—An obvious defect in the enamel may not be apparent although an abscess be concealed at the root of the tooth. Careful examination along the gum may reveal the discharging point of a "gum boil." Local lymphatic swelling and tenderness can be discovered. x-Ray examination makes the diagnosis clear.

Roseola Infantum—Exanthem Subitum.—This is a disease occurring only in infants and children under three years of age. The fever is high, 103° to 105° F., for several days before any physical signs beyond a mildly reddened throat may be discovered. At the end of this period the temperature falls by crisis, a nondescript rash of the German

measles type makes its appearance, and the child is well. Unlike German measles this disease has no postauricular nor post-cervical glandular enlargement.

Scurvy.—Irritability, not fever, is the real characteristic of scurvy. Fever is very likely to occur, however, and may be of extreme degree when a hemorrhage reaches the thalamic region. All the signs and symptoms of this disease are due to the same cause, namely, the extravasation of blood and the distentions caused by it. This hemorrhage is most easily visible on the gums about the teeth. Where none are present, this sign is of little value. Along the bones the hemorrhage is subperiosteal, causing great pain and swelling. On the long bones it begins at the epiphyseal ends of the shaft. Because of the proximity to the joint the swelling seems to involve the articulation itself. Subperiosteal hemorrhage may be of great severity even to the production of dislocation fractures. Over the flat bones the same type of hemorrhage occurs and may progress to the production of exophthalmus.

The use of the tourniquet to produce capillary hemorrhage as a diagnostic means is not reliable. In some cases of scurvy petechiae are readily produced, in others it is impossible to produce them. α -Ray evidence of the disease appears early.

Aspiration of sterile blood distinguishes the condition from osteomyelitis. This aspiration is seldom necessary as α -ray evidence is obtainable at this stage. A therapeutic test of giving vitamin C should be performed simultaneously with other methods for establishing the diagnosis.

Osteomyelitis.—A history of an injury followed by a fever and a deep bone pain make this an evident diagnosis. In infants it can be much more obscure. Fever of increasing height is inevitably present. Prostration soon ensues. Pain, as evidenced by the irritability and moaning cry, is early and constant. One finds swelling over the involved area with sharply demarcated tenderness of extreme degree. The regional lymph nodes are enlarged and tender. The differential diagnosis usually resolves itself into a differentiation of this condition from rheumatic fever. This may not be easy.

Osteomyelitis is a much more severe infection in its local manifestations than rheumatic fever. It does not affect more than one area. The systemic signs, such as prostration, chills, and convulsions, are more usual and severe in the early stage. The white blood count and polymorphonuclear proportion is much higher than in rheumatic fever. There may be apparent joint involvement in osteomyelitis but the point of greatest tenderness is over an epiphysis adjacent to the joint itself.

Unfortunately neither condition has roentgenogram evidence in the early stages. After ten days there is a characteristic x-ray picture of osteomyelitis.

Rheumatic Fever.—The course of this disease is one of the most variable of the complaints of childhood. Its only stable feature is the rarity of its onset prior to the fourth year of life. Its course may range from indeterminate muscle and joint aches and pains to those scarcely distinguishable from osteomyelitis. The fever may be so slight as to be overlooked by the mother or so severe that it is septic in type. In the milder forms there may be nothing to be found until the heart begins to show involvement. Fortunately the usual case furnishes physical evidence of disease. Fever following a streptococcic sore throat or other infection makes one suspect the milder forms. Frequent nosebleed and loss of appetite are premonitory signs. Physical examination occasionally reveals subcutaneous nodules over the malleoli, the extensor tendons of fingers and toes, the scalp, and around the knees and elbows. There may be joint stiffness and abdominal pain. A postnasal drip is often present as rheumatic fever is frequently associated with pharyngitis and tonsillitis. Erythema nodosa and erythema multiforme, especially the former, are so often found in this disease that many examples of those syndromes are assumed to have a rheumatic origin. The joint involvement is one of painful motion, swelling and tenderness. It commonly attacks several joints simultaneously or successively. In this it is quite different from osteomyelitis. The laboratory reports an increased white blood cell count with a shift of the Schilling index to the left and a rapid sedimentation rate. None of

these are specific for rheumatic fever but are constant findings with it. The degree of leukocytic response may be great but not so great as a pyogenic infection would summon.

Undulant Fever—*Brucella Melitensis*—Malta Fever.

—Fever is one of the few constant signs found in this disease. It is associated with chills, loss of weight, increased sweating and loss of appetite. There may be constipation, abdominal pain and backache. Headache and cough with excessive nervousness and weakness are other symptoms found in this condition. Joint pain and deep bone pain are not uncommon. On examination one finds pronounced pallor, enlarged cervical nodes and commonly moderate enlargement of the spleen. The skin may have indeterminate macules and papules.

The laboratory is able to give definite evidence toward this diagnosis. The blood, urine, and duodenal contents will supply the organism when cultured in carbon dioxide. The agglutination phenomenon appears after the seventh day of the disease. The white blood count reveals a leukopenia. A cutaneous test for this disease is performed with a heat-killed broth culture of brucella diluted 1:100. Redness in forty-eight to seventy-two hours indicates past or present infection.

Tularemia.—The onset of this disease is initiated by fever, chills and general malaise which may increase to prostration. When the history is taken it is found that the child has been in close contact with a rodent, usually a rabbit. There is a generalized lymph gland enlargement. The cervical nodes are frequently conspicuously swollen and sometimes the disease attacks the eye, giving a severe ophthalmitis. Fever is constant in type, pursuing a characteristic course. Its duration is from one to three weeks. It has an initial rise of two or three days followed by a remission for about the same length of time and a second rise and slow fall to normal. A maculopapular rash may appear during the course of the disease. Diagnosis can be established clinically through the use of a skin test which consists of a vaccine of *Bacterium tularense* diluted 1:10,000. An area of redness appears at the site of

injection in thirty minutes to forty-eight hours if there be infection.

Rocky Mountain Spotted Fever.—This tick bite fever is known to occur far more widely than in the Rocky Mountain region to which it was thought restricted. Recently many cases have been reported along the Atlantic seaboard. It should be anticipated in all parts of the United States. The disease is transmitted by ticks, the *Dermacentroxenus rickettsii* being the organism involved. This disease is similar to typhus in all but two particulars. It has a shorter incubation, two to five days, and its rash begins at the wrists extending centripetally to involve the body. In all other respects the diseases are identical. See Typhus.

Typhus Fever—Brill's Disease.—This disease, like Rocky Mountain spotted fever, is caused by a rickettsia. In the case of typhus it is *Rickettsia prowazeki*. This organism is carried by lice and bedbugs. Its incubation period is twelve or more days. Typhus and Rocky Mountain spotted fever are identical in their course. Both have sudden severe onsets with fever, chills, and prostration. The temperature rises and stays elevated continuously. About the fourth day the rash makes its appearance. In typhus the rash begins in the axillae and extends centrifugally to involve the extremities and in so doing may be distinguished from Rocky Mountain spotted fever which spreads centripetally. Both have headache, nausea, vomiting and frequently backache and joint pains are present. Coma and delirium commonly ensue. The rashes in both are maculopapular and petechial. In both the skin signs may be accentuated by the tourniquet test. In both there is leukocytosis. The Weil-Felix agglutination reaction makes its appearance about six weeks to two months after convalescence. This is the agglutination of cultures of X19 or X2 in dilutions of 1:80 or greater, by the serum of the patients. Guinea-pig inoculation of the patient's sputum may show results before this time. The urine gives positive diazo reactions.

Rat-bite Fever.—As its name suggests this disease is

transmitted through the bites of rats. The organism present is the *Borrelia muris* (*Spirochaeta morsus muris* or *Spirillum minus*). The disease has an incubation period of two weeks after which there is a sudden onset of fever accompanied by chills and prostration. Muscle and neuralgic pains are marked. A bluish-red maculopapular rash appears after the height of the disease is reached. Spirochetes can be demonstrated by the dark-field method in the blood or the wound. The urine not uncommonly contains them as well. Guinea-pig inoculation will reproduce the disease.

Relapsing Fever.—This condition also is caused by infection with one of the various species of *Borrelia*. It is characterized by periods of fever alternating with normal temperatures each lasting five to seven days. It probably is transmitted by lice or bedbugs. There is a prolonged, recurrent fever which brings chills, muscle and joint pains, headache, vomiting and nausea with it. The spleen and liver are enlarged. On the skin are multiple petechiae. The laboratory findings are the same as for rat-bite fever.

Malaria.—Malaria in the child can present quite a different picture from that in the adult. The younger the child, the greater may be the variation. There is no maternal immunity transferred in this disease. Congenital cases have been described. Children acquire all three types of the disease but in the child they can seldom be distinguished by their clinical courses. Regular recurrences of the febrile attacks may be entirely absent. Chills, so common in the adult, may take the form of muscle pains in the child. The duration of the fever on each rise is shorter in childhood and the fever is more likely to occur at night than in the morning as in the adult.

The children with malaria complain of listlessness, weakness and anorexia. An attack of fever is ushered in by cold extremities, cyanosis and vomiting. One third of them have convulsions. Anemia of a hemolytic type appears and becomes progressively worse. Leukopenia may or may not be present. Hemic murmurs, enlarged hearts, and gallop rhythm occur in the more chronic cases. The spleen becomes en-

larged in the chronic ones while in the more acute the liver is more regularly swollen. In infants the liver is more frequently enlarged than the spleen.

Malaria Inoculata.—More and more cases of malaria are occurring following blood transfusion. The incubation period depends upon the number of parasites transferred, as in other malaria, and may be as short as three days. Commonly, it is two weeks. The course is that of malaria acquired in the usual manner. See Malaria.

Hodgkin's Disease.—This disease is characterized by a glandular enlargement of disputed etiology. The glands involved commonly are the left cervicals. These may be left unscathed and only the mediastinal or retroperitoneal glands touched by the disease. In any case there is a low-grade, variable fever of a recurrent order. Accompanying the fever is a loss of weight and appetite. In the further advanced cases vomiting and nausea, abdominal pain, cough, dyspnea, and epistaxis and bleeding gums may be present. Marked itching is frequently a source of discomfort to the patient. Pallor, jaundice or cyanosis may be found on inspection. The liver and spleen are enlarged and ascites occasionally occurs. The diagnosis can be established by biopsy and Gordon's rabbit inoculation test. The blood picture shows an increase in the number of platelets and monocytes. Eosinophils usually are only slightly, but may be enormously, increased. There is a uniformly widened mediastinal shadow on the x-ray plate.

Pel-Ebstein Hodgkin's Disease.—In this form of the disease there is a complete remission of fever at regular intervals. See Hodgkin's.

Leukemia.—In both the lymphatic and the myelocytic types of leukemia there is a prolonged or recurring fever usually of low degree. In both types chills accompany the rise in temperature. The symptoms are those of capillary hemorrhage. They may include cough, dyspnea, epistaxis, deafness, sore mouth, dysphagia, bleeding gums and anorexia, abdominal pains, nausea, vomiting and diarrhea. Should the hemorrhage strike the nervous system paralyzes of any order may

be encountered as well as sensory alterations. Pallor, jaundice, petechiae, retinal abnormalities, blood per rectum, may be expected on examination. The stool and urine may have positive benzidine tests or even gross blood. In the lymphatic type of leukemia cervical nodes, salivary glands, axillary glands and generalized enlargement is to be expected. In the myelocytic leukemia one finds liver enlargement primarily. Blood studies expose the nature of the malady.

Acute Infectious Mononucleosis—Glandular Fever.—

After an incubation period of four days to two weeks the onset suddenly occurs. Fever of 102° F., or more, headache, stiff neck and general malaise are regularly present. After four days glandular enlargement begins to be evident. The cervical nodes are especially affected. These are distinctly tender to the touch. There may be pain in the abdomen. The spleen enlarges in most instances and also the liver in the more severe involvements. There is no rash. In the early phase a leukocytosis with a high polymorphonuclear percentage may be found. This picture changes shortly to a preponderance of lymphocytes with many immature cells visible. Although the lymphocytes are increased both relatively and absolutely they are never of the high percentages found in the leukemias. Heterophil antibodies can be demonstrated.

Sickle Cell Anemia; Sicklemia.—This form of anemia is prevalent only among the colored race. It has been reported rarely among the Mediterranean peoples but seems not to attack the Anglo-Saxon. In Negroes sickling can be demonstrated in a high percentage but few develop the subsequent anemia. The disease is named from the form the red blood cells assume on standing in a moist preparation. The onset may occur at any age and may be either mild or severe. Commonly, a febrile attack marks the beginning of this progressive, hemolytic anemia. Weakness, lassitude, anorexia and a very low-grade fever may obscure the true diagnosis. Yellow-green sclerae, generalized itching, muscle and joint pains are frequently observed. Dyspnea, abdominal pain accompanied by vomiting, palpitation, numbness and tingling or paralysis, may

occur in the progress of this disease. One finds heart murmurs, enlargement of the spleen and occasional enlargement of the liver, on examination. Clubbed fingers are not uncommon. Delayed physical and sexual development occur in the more severe cases of this condition. Besides the sickling the blood shows evidence of hemolysis. There is a reduced fragility of the red blood cells. The hemoglobin falls to a low level and nucleated and reticulated forms of red blood cells appear. The urobilin is greatly increased in both stools and urine. An indirect van den Bergh reaction can be detected in the blood.

Psittacosis—Parrot Fever.—This disease may be contracted from any of the parrot family including macaws and parakeets. There is a sudden onset with a high fever. Nose pain and discharge is one of the usual early complaints of the victims. Cough and dyspnea, or nausea and vomiting and diarrhea soon appear. A macular rash occurs at the height of the disease. Diagnosis can be established by intraperitoneal injection of the sputum from infected patients into mice. Characteristic psittacosis bodies appear in the spleen of the mice so inoculated. Since the same result can be produced from either filtered or unfiltered sputum Rivers and Berry conclude that the causative organism is a virus.

Paroxysmal Hemoglobinuria.—Recurrent febrile paroxysms associated with hemoglobin in the urine give this disease its name. The attacks follow exposure to cold or the immersion of the hand or feet in cold water. Each attack is accompanied by chills, and nausea and vomiting. Generalized urticaria may be present. Pains in the back, the abdomen and the extremities frequently occur. The spleen is moderately enlarged.

The disease is likely to be a result of congenital syphilis. The Wassermann reaction should always be determined. An autohemolysin can be demonstrated by mixing the patient's red blood cells with his own serum at 0° C. for seven minutes. After this length of time the blood should be incubated at 37° C. for one hour (Donath-Landsteiner reaction). An attack

can be precipitated by immersion of the feet in ice water for one-half hour.

Purpura.—It is inaccurate to classify purpura as a clinical entity. It is a sign of disease but since it can, and does, occur as the major physical finding in some conditions it may be discussed here. It receives its various names from its predominating symptom or from its cause. Thus there is purpura rheumatica or Schoenlein's purpura, and purpura abdominalis or Henoch's purpura, as well as cachectic purpura, urticarial purpura and thrombocytopenic purpura. This last is the one of importance to this discussion. The attacks usually are initiated by a febrile period. This is of moderate elevation in the usual case. It may be slight indeed so that the purpuric areas are noted first and the temperature determined merely as a routine procedure. In these children pallor, headache, loss of appetite may be the reason for consultation with a physician. More frequently the onset is more violent. The symptoms and signs may be of any or all the systems depending upon the site of the hemorrhages. Thus there may be retinal abnormalities, deafness, epistaxis, bleeding gums and vomiting, hematuria, and hematemesis, bloody diarrhea and abdominal pain. There may be paralysis and disturbances of sensation. It may resemble meningitis. In the rheumatic purpura joints are swollen and painful. Of course, in the abdominal type symptoms relating to the gastro-intestinal tract predominate.

The diagnosis can be verified by laboratory means. The platelets which normally number 250,000 to 300,000 may be as low as 50,000 or less. The clotting time is within normal limits but the bleeding time is definitely prolonged. The tourniquet test, while not specific, may be of value as a clinical adjunct. Purpuras of the cachectic, and urticarial types, and those due to poisons, blood dyscrasias or scurvy do not have a reduction in the number of platelets.

Subacute Bacterial Endocarditis.—This disease does not exist in an undamaged heart. The damage may be slight, however, and difficult to demonstrate. History of a previous

rheumatic fever may be of great value in establishing the diagnosis. In subacute bacterial endocarditis there is a protracted fever with an accompanying pallor and debility. Physical signs other than those found in the heart itself may be greatly delayed in appearance. Enlargement of the spleen occurs at times. Electrocardiographic tracings will assist in the demonstration of heart damage. Orthodiagrams by the roentgenologist may be of value, but close clinical observation will eventually discover it. When it is known that there is heart damage this diagnosis becomes less obscure as a cause of fever. Characteristically subacute bacterial endocarditis progresses to give multiple minute emboli. These are most easily visible in the conjunctivae but cause more marked symptoms when they strike the capillary bed of a finger. Blood culture, however, will often demonstrate the presence of subacute bacterial endocarditis before any of these findings are evident.

SYMPOSIUM ON COMMON OBSTETRIC AND GYNE- COLOGIC PROBLEMS OF THE FAMILY PHYSICIAN

The following clinics are included in this Symposium:

P. Brooke Bland and Arthur First: STERILITY.

Norris W. Vaux: DIAGNOSTIC MISTAKES IN GYNECOLOGY.

Franklin L. Payne: THE CAUSES OF ABNORMAL VAGINAL BLEEDING DURING
THE PRE- AND POSTMENOPAUSAL AGES.

Margaret Castex Sturgis: TREATMENT OF HABITUAL ABORTION.

Aaron Capper: THE DIAGNOSIS AND TREATMENT OF CYANOSIS OF THE NEWBORN.

Thomas J. Costello: TREATMENT OF CHRONIC ENDOCERVICITIS AND VULVO-
VAGINITIS.

CLINIC OF DRS. P. BROOKE BLAND AND ARTHUR FIRST

DEPARTMENT OF OBSTETRICS, JEFFERSON MEDICAL COLLEGE

STERILITY

A PROPER study of a barren marriage requires equal attention to the male and female. So conspicuous is the incidence of male responsibility in our clinic that in more than 50 per cent of the patients the two mates are receiving treatment simultaneously. Every effort should be made to raise the fertility index of the male as high as possible, thus indirectly increasing the fertility of the wife with a low index.

Male Responsibility.—Sterility in the male may be due either to congenital or acquired conditions of the testicle, vas deferens, epididymis, prostate gland or penis, which interfere with proper development of the spermatozoa, or with the conveyance of living sperms to the genital organs.

A lowered fertility in the male may also result from either functional or organic nervous disease, especially those associated with impotence. Organic lesions may cause azoospermia, a total absence of spermatozoa; oligospermia, a marked diminution of spermatozoa; or necrospermia, the presence of feeble or dead spermatozoa.

Most of these conditions result from gonorrheal infection. Gonorrhea is a preponderating cause in both primary and secondary sterility. The toll that gonorrhea exerts in unborn lives is utterly impossible to determine or even guess, but it is believed that from 30 to 50 per cent of sterile marriages result from this disease.

Endocrine hypofunction, depressed constitutional states, exhaustion from sexual excess or obstruction in the passages

may be responsible factors. It is necessary, therefore, to obtain a genito-urinary history and make a thorough examination of the husband.

Accurate observation of the morphology, vigor and persistence of sperm motility as obtained from a condom specimen and a postcoital examination of the cervical canal are important in properly appraising male fertility.

Azoospermia is relatively infrequent, being encountered in only 5 per cent of sterile marriages whereas oligospermia is noted in over 50 per cent. The mere finding of live sperms does not absolve the male, as the chances for impregnation are in direct ratio to the number and vitality of the spermatozoa.

Normal Male Fertility.—A normal specimen (preferably obtained from a glass jar, warmed to body temperature and examined not later than one hour after intercourse) should reveal the following:

(1) 50 to 100 live sperms per high-power field.

(2) A one- to two-hour resistance to room temperature, the spermatozoa remaining motile on a slide under the microscope.

(3) A large number of dead sperms.

Lowered fertility is indicated when one observes a large number of amyloid bodies or more than 5 pus cells per high-power field.

Moench claims that a morphologic and biometric examination of the semen offers a method for ascertaining male fertility. A normal fertile man ejaculates less than 15 per cent abnormal sperm heads. If the head abnormalities rise to between 20 and 25 per cent, impaired fertility is to be assumed and above 25 per cent, sterility. The number of these abnormal sperm heads indicates the degree of spermatogenic disturbance and that the other sperm heads, although they may appear normal under the microscope, may not be normal.

Macomber made counts of spermatozoa and found variations between 300 million and 100,000 organisms per cubic centimeter. A count below 60 million per cubic centimeter indicates low fertility in which the sex cells seem to suffer.

According to Kurzrok and Miller, semen exerts a highly specific lytic action on the mucin of the cervix. Tests made with mucus from patients with leukorrheal discharge indicate that the digesting action of normal semen is markedly diminished by the presence of inspissated mucus. If a drop of seminal fluid is placed alongside a drop of cervical mucus under a coverglass, a number of sperms should normally pass through the cervical drop within one hour. The lytic substance of the semen may be essential in the passage of spermatozoa up the genital tract and its absence may be an etiologic factor in some cases of sterility for which no other explanation can be offered.

Postcoital Examination.—Cervical insemination and favorable cervical secretion are essential for the proper transmission of spermatozoa. Huhner's test which includes investigation of semen activity in the vagina and all levels of the cervical canal to the internal os, is of inestimable value. Spermatozoa seldom survive more than two hours in the vaginal pool (receptaculum seminis), but may retain vigorous motility in the normal cervix for from sixteen to twenty-four hours. The finding of nonmotile spermatozoa in the cervical canal may be due to necropermia or to hostility of the cervical secretion. It is essential to examine a condom specimen to differentiate the two conditions. A postcoital examination should be made four to six hours after intercourse. Normally 5 to 10 sperms per high-power field are obtained from the aspirated cervical canal secretion. If less are found, it is assumed that coitus is faulty or that the cervix has not been properly inseminated.

Sterility of the Female.—*Investigation.*—A complete and comprehensive study of the female factors in the production of sterility, includes:

1. A careful general and gynecological history.
2. A complete physical examination with special emphasis upon endocrine and pelvic study.
3. Complete laboratory studies including a serological blood test, a routine blood count, a urine examination, a basal metabolic rate determination, an estimation of the blood chol-

esterol, a premenstrual determination of the estrin hormone in the blood, an estimation of the pituitary blood hormone, a determination of the urinary excretion of estrin and anterior pituitary hormone, a study of the specific dynamic action of protein, a glucose tolerance test, eyeground and visual field examinations and a roentgenogram of the sella turcica.

4. A special gynecological examination including a study of the endocervical secretions, a postcoital examination, a tubal insufflation and, if necessary, a subsequent lipiodol injection and a premenstrual curettage to determine the presence or absence of a normal premenstrual nidatory endometrium.

Etiology.—The factors responsible for sterility in the female may be divided into general causes, local causes, and functional disorders. Usually there are several abnormalities coexisting.

General Causes.—1. *Infections.*—The acute infections, influenza, typhoid fever, mumps, scarlatina, tonsillitis, acute rheumatic fever, and acute puerperal fever may cause secondary ovarian infections and result in atrophy and sterility. Focal infection may likewise be responsible.

2. *Chronic systemic diseases* such as diabetes, renal and pulmonary disease, or profound anemia are not uncommonly associated with sterility. Chronic alcoholism, morphinism and cocaineism are also associated with sterility while in organic and functional nervous conditions, impregnation is not likely.

3. *Consanguinity.*—Sterility is not uncommon in the union of blood relations, although it is not an absolute barrier.

4. *Selective sterility* (incompatibility) refers to those individuals who do not bear offspring, although both may be fertile when united to other partners. This type is not infrequent. The cause is not known. It perhaps resides in both partners who are of low fertility, although either partner may produce offspring in a highly fertile mate.

5. *Physiological Causes.*—Women are sterile during certain physiological states, as in pregnancy, except in those rare cases of superfetation in the normal or in the double uterus. Frequently women are sterile at certain periods (safe period)

and for this reason the sexual relation is indulged in by these individuals only at this time. Physiologic sterility is, however, debatable. Knaus contends that women who menstruate every twenty-six to twenty-eight days can only conceive from the ninth to the fifteenth day of the cycle whereas those who bleed every twenty-eight to thirty days are capable of fertilization only between the eleventh and seventeenth days of the cycle.

Local Causes.—1. *Congenital Underdevelopment of the Genital Organs.*—This is one of the most common local causes of sterility either in the form of a rudimentary vagina or uterus, stenosis of the vagina or cervix, or an imperforate hymen.

2. *Faulty Cervical Insemination.*—It is essential that the semen reach the cervical canal directly. Severe lacerations of the vagina with prolapse of its walls, and of the cervix, allowing escape of the seminal fluid, are provocative of sterility. Dyspareunia, resulting either from psychic conditions or lesions of the vulva and vagina, may be responsible. Urethral caruncles which are extremely sensitive may set up a vaginismus. Kraurosis vulvae may not permit sexual access to be completed.

3. *Hostility of the Endocervical Secretion.*—Hostility of the cervical secretion is indicated when one finds only dead spermatozoa in this material six hours after coitus, especially if normal sperms at the same time are found in the condom specimen. Acid cervical secretions inimical to the sperms are usually found in women without infection. This biochemical incompatibility is more often associated with poor cervical drainage or ovarian deficiency with hypoplastic generative organs and precludes fertility. The hydrogen ion concentration of cervical secretion varies between 8 and 9 (*i. e.*, definitely alkaline). An excessively high acidity may occasionally cause sterility, although this is infrequent, as normal vaginal acidity is due to lactic acid which practically never exceeds 0.5 per cent. In this spermatozoa may live for hours. The hostility of excessive acid vaginal secretion has been confirmed

by conception occurring after neutralization or alkalization of the vaginal secretion.

4. *Displacement of the uterus* is not a cause of sterility if proper insemination of the cervix takes place as noted after a postcoital examination. It may, however, be indirectly responsible from the complicating inflammatory lesions of the lining membrane or the wall or by interfering with the circulation of the ovaries. Uterine abnormalities are often accompanied by other conditions which render conception impossible. Thus an infantile uterus may be associated with sterility because of infantile ovaries failing to ovulate. Acute antelexion with cervical stenosis is seldom responsible for sterility. The easy introduction of a sound with the thickness of from 2 to 4 mm. into the cervical canal is proof that no obstruction to the ascent of spermatozoa is present.

5. *Tumors*.—Neoplasms of all types, especially those involving the endocervix or the endometrium, as polyps, for example, may, if developing early, result in absolute sterility; if later, relative sterility. Fibroid tumors are the most common forms of neoplasms associated with sterility. Submucous myomas by obstructing the uterine ostia of the tubes may prevent conception or by encroaching upon the uterine cavity may cause abortion. Conception, however, may occur in fibroid of the interstitial and subserous type, especially if these are not complicated by endometrial, tubal or ovarian disease.

6. *Stenosis of the Tubes*.—Partial tubal obstruction is a common cause of extra-uterine pregnancy. Complete tubal occlusion is the most frequent cause of sterility. This may be the result of spasm, a developmental defect or an antecedent inflammation. Acquired tubal stenosis is usually gonorrheal in origin, though it may follow abortion, appendicitis, peritonitis or intra-uterine infections. Retroversion is cited as a common cause of tubal kinkage.

7. *Ovarian Sterility*.—This may be congenital or acquired. In the congenital type there is a retarded development of the ovaries closely associated with other endocrinopathic irregularities. In the acquired type inflammation of the ovaries re-

sulting in hyperplasia or sclerosis is not an uncommon cause of sterility. The antecedent pelvic infection, usually gonorrheal in origin, results in a thickened tunica albuginea which impedes maturation and rupture of the graafian follicle. Failing to rupture, the follicles become the seat of cystic degeneration. In these patients, there is often an associated endometrial hyperplasia producing prolonged menstrual flow. If ovulation does occur, an existing infarcted and hemorrhagic endometrium often prevents conception. Ovarian abscess due to gonorrhea or tuberculosis may cause complete destruction of the sexual glands. Ovarian cysts by destroying the ovarian structure or by compressing the tubes may likewise cause sterility.

8. *Contraceptives and Sterility*.—Various contraceptive measures resorted to in the first two years of marriage may produce hostile secretions and chronic pelvic congestion inimical to conception. The use of intra-uterine stems may well be considered as a cause, because of irritation, erosion and infection of the uterus and tubes. The use of strong vaginal antiseptics, as undiluted bichloride of mercury, may also be mentioned as causative.

Functional Sterility.—The interpretation of sterility in patients in whom a complete physical examination reveals no anatomic abnormalities in either husband or wife is a complex problem, requiring for satisfactory solution among many things an understanding especially of the interrelationship of the glands of internal secretion.

In dealing with sterility of assumedly endocrine origin, it is of paramount importance to determine, if possible, which gland is primarily responsible. From the angle of investigation, functional sterility may be conveniently divided into clinical and laboratory aspects.

Etiologically, cases of functional sterility may be due chiefly to primary pituitary, ovarian or thyroid dysfunction.

A. Primary Pituitary Deficiency.—Primary deficiency of the anterior pituitary lobe is by far the most common form of endocrine disturbance encountered in sterile patients. Generally speaking, this condition, if not sufficiently severe to

suppress totally ovarian function, is usually one of a mild Fröhlich's syndrome (adiposogenital dystrophy). Clinically, these patients are rather short in stature and show distinct stigmas of underactivity of the hypophysis, manifested, first, by a characteristic mammary-mons girdle obesity due to associated involvement of the hypothalamus; secondly, by hypertrichosis with masculine distribution of pubic hair, and thirdly by genital hypoplasia with menstrual derangements.

B. Primary Ovarian Failure (Primary Hypogonadism).—Primary ovarian failure is due to inherent deficiency of the internal secretory portion of the ovary independent of the secondary effects of the diminution of function of other glands, notably the pituitary and thyroid. Clinically, these patients present a marked contrast to those of the hypopituitary type. They represent the superlatively feminine type. They are emotional to excess, underweight, visceroptotic and intolerant to food, and experience gastro-intestinal spasticity and irritability of the nervous system.

Hypoplasia of the genital organs and irregular menstruation or amenorrhea are constant observations. Hormone studies reveal a uniformly low estrogenic level in the blood premenstrually. The most significant finding, however, is a demonstrable quantity of anterior pituitary gonadotropic hormone in the blood and urine in about 50 per cent of the patients.

C. Thyroid Derangement.—Thyroid dysfunction either in the form of hypoactivity or hyperactivity not infrequently is a cause of sterility.

The diagnosis is relatively easy, provided one resorts as a routine to basal metabolic studies in the investigation of functional sterility.

Hormone Studies.—The determination of ovarian (estrogenic) and pituitary (gonadotropic) hormones in the urine is an extremely valuable laboratory adjuvant in the diagnosis and treatment of the underlying condition as well as of allied menstrual disorders.

Study of the Endometrium.—The endometrium obtained

after a diagnostic premenstrual curettage yields valuable information regarding the presence of a suitable nidatory site for the implantation of a fertilized ovum. The absence of a normal secretory premenstrual phase is indicative of failure of ovulation or of a deficient corpus luteum and explains many problem cases of sterility in the regularly menstruating woman.

Treatment of Sterility.—A thorough knowledge of the etiological factors involved must be obtained before any course of treatment is outlined. For this reason the cooperation of gynecologist, urologist and internist in a well-organized sterility clinic is essential for a proper study of the problem.

Diet.—A diet low in calcium has considerable effect in reducing fertility and may even favor miscarriage. A high protein and vitamin E diet, low in calories, with the administration of calcium lactate and enough exercise to assure assimilation, is recommended. Diet is also of great value in the treatment of associated anemia or obesity. While obesity may not be the cause of sterility, it is frequently associated with evidences of diminished ovarian function which is improved by weight reduction.

Vitamin E in Relation to Sterility.—In the male a diet rich in vitamin E is more important than in the female. In the woman, abortion, it is believed, can be prevented by a diet rich in vitamin E. The substance is found widespread in the organs of certain plants, especially in green leaves and seeds. It is abundant in wheat germ, peas, alfalfa, lettuce, spinach and other leaves. In wheat, it is stored exclusively in the germ. In fact wheat germ oil constitutes one of the highest known sources of the vitamin. It is present in small quantities in animal tissues and in milk. It is absent in the tissues of animals which have been deprived of this vitamin by some special type of artificial feeding.

It has been suggested that vitamin E should be termed "anti-abortion vitamin," rather than antisterility vitamin.

Tubal Insufflation.—The Rubin test as a therapeutic measure has recently been brought to the fore. Pregnancy may follow insufflation by separating mild agglutinations and

straightening tortuous tubes. This is demonstrated by actual improvement in tubal pregnancy and function during prolonged or repeated insufflation as recorded on the kymograph, and by pregnancy which follows soon thereafter. As many as 18 tests may be performed before pronouncing a patient as hopeless.

Treatment of Functional Sterility.—In considering the treatment of functional sterility, it is of course clear that prophylaxis in the adolescent youth is of the utmost importance. A large number of functionally sterile women cite a history suggestive of glandular disturbance in early adolescence. The resulting incomplete development of the genital organs should, therefore, be guarded against at this period in order to avoid the possibility of sterility in later life. All endocrine disorders should be treated at once. It is indeed unfortunate if initial complaints referable to a disturbed genital physiology are ignored.

Optimal Time of Conception.—Too frequent intercourse may empty the epididymis of sperms before they are ripened and thus cause sterility.

Recently, renewed interest has been manifested in the age-old question as to the most favorable period of impregnation. Generally speaking, one may say that conception is most frequent after coitus following ovulation. Sterility, therefore, may be due in some cases to the fact that coitus occurs only during the period of "physiologic sterility." If a woman menstruates every twenty-eight to thirty days, conception is most likely to take place between the eleventh and seventeenth day after the beginning of the period. If she has a cycle of forty days, her most fertile period is fourteen days before the expected flow.

Organotherapy.—Despite the noteworthy advance made in the manifold aspects of endocrinology, organotherapy until quite recently was almost void of accomplishment. In all instances the correction of menstrual irregularities is of vital importance in the treatment of functional sterility.

A. Thyroid.—This is a most valuable adjuvant in the treatment of functional sterility and may be used even when

the basal metabolism is normal or slightly subnormal. The administration of desiccated thyroid tissues, $1\frac{1}{2}$ or 2 grains (0.09 or 0.13 Gm.) daily, tends to increase cellular activity throughout the entire body, including the endocrine glands. In addition, it has been shown that thyroid neutralizes the effects of estrogenic substance on the endometrium, which may explain the temporary beneficial effects of thyroid therapy in functional uterine bleeding when prolonged and unantagonized action of estrogenic substance on the endometrium is the immediate cause of abnormal bleeding itself.

B. *Estrogenic Substance*.—It must be remembered that, despite restoration of pituitary function, the marked uterine atrophy, either primary or as a result of a preexisting pituitary deficiency, may in itself become the cause of the continued amenorrhea and sterility. Estrogenic substance has no effect on the ovary, but it does evoke an increase in growth and vascularity of the uterus and renders it, therefore, more responsive to improved or normal ovarian stimulation.

It has been determined by Mazer that 1000 rat units administered hypodermically every third day or 1000 rat units orally, in three divided doses daily, will maintain the normal estrogenic level in the castrated woman. This high dosage, however, is not required in the ordinary case of sterility, because in these patients there is actually some degree of ovarian function. It becomes necessary, therefore, to determine the excretion of estrogenic substance in the urine and blood and, if below normal, to administer an amount sufficient to maintain a normal level of daily urinary excretion. A woman who shows one half of the normal level of estrogenic substance should receive only one half of the full therapeutic dose.

C. *Anterior Pituitary-like Gonadotropic Hormone*.—The administration of anterior pituitary-like gonadotropic substance in 200 rat units combined with anterior pituitary lobe extract, 2 cc. given every other day for ten weeks, may increase the fertility index. It is moderately successful in irregularly menstruating women in stimulating luteinization and in creating an endometrium favorable for nidation.

straightening tortuous tubes. This is demonstrated by actual improvement in tubal pregnancy and function during prolonged or repeated insufflation as recorded on the kymograph, and pregnancy which follows soon thereafter. As many as 18 tests may be performed before pronouncing a patient as hopeless.

Treatment of Functional Sterility.—In considering the treatment of functional sterility, it is of course clear that prophylaxis in the adolescent youth is of the utmost importance. A large number of functionally sterile women cite a history suggestive of glandular disturbance in early adolescence. The resulting incomplete development of the genital organs should therefore, be guarded against at this period in order to avoid the possibility of sterility in later life. All endocrine disorders should be treated at once. It is indeed unfortunate if initial complaints referable to a disturbed genital physiology are ignored.

Optimal Time of Conception.—Too frequent intercourse may empty the epididymis of sperms before they are ripened and thus cause sterility.

Recently, renewed interest has been manifested in the age-old question as to the most favorable period of impregnation. Generally speaking, one may say that conception is most frequent after coitus following ovulation. Sterility, therefore, may be due in some cases to the fact that coitus occurs only during the period of "physiologic sterility." If she has a cycle of forty days, her most fertile period is fourteen days before the expected flow.

Organotherapy.—Despite the noteworthy advance made in the manifold aspects of endocrinology, organotherapy until quite recently was almost void of accomplishment. In all instances the correction of menstrual irregularities is of vital importance in the treatment of functional sterility.

A. Thyroid.—This is a most valuable adjuvant in the treatment of functional sterility and may be used even when

the basal metabolism is normal or slightly subnormal. The administration of desiccated thyroid tissues, $1\frac{1}{2}$ or 2 grains (0.09 or 0.13 Gm.) daily, tends to increase cellular activity throughout the entire body, including the endocrine glands. In addition, it has been shown that thyroid neutralizes the effects of estrogenic substance on the endometrium, which may explain the temporary beneficial effects of thyroid therapy in functional uterine bleeding when prolonged and unantagonized action of estrogenic substance on the endometrium is the immediate cause of abnormal bleeding itself.

B. Estrogenic Substance.—It must be remembered that, despite restoration of pituitary function, the marked uterine atrophy, either primary or as a result of a preexisting pituitary deficiency, may in itself become the cause of the continued amenorrhea and sterility. Estrogenic substance has no effect on the ovary, but it does evoke an increase in growth and vascularity of the uterus and renders it, therefore, more responsive to improved or normal ovarian stimulation.

It has been determined by Mazer that 1000 rat units administered hypodermically every third day or 1000 rat units orally, in three divided doses daily, will maintain the normal estrogenic level in the castrated woman. This high dosage, however, is not required in the ordinary case of sterility, because in these patients there is actually some degree of ovarian function. It becomes necessary, therefore, to determine the excretion of estrogenic substance in the urine and blood and, if below normal, to administer an amount sufficient to maintain a normal level of daily urinary excretion. A woman who shows one half of the normal level of estrogenic substance should receive only one half of the full therapeutic dose.

C. Anterior Pituitary-like Gonadotropic Hormone.—The administration of anterior pituitary-like gonadotropic substance in 200 rat units combined with anterior pituitary lobe extract, 2 cc. given every other day for ten weeks, may increase the fertility index. It is moderately successful in irregularly menstruating women in stimulating luteinization and in creating an endometrium favorable for nidation.

D. *Insulin*.—This preparation employed in a dose of 10 units administered one-half hour before breakfast and dinner is chiefly effective in cases of primary ovarian failure. Not only is body weight increased, but distinct improvement in genital function is noted.

Irradiation.—Low dosage irradiation of the pituitary gland and ovaries affords the best results in the treatment of menstrual disturbances with functional sterility associated. Strict adherence to all the technic laid down by the roentgenologist is most essential, *i. e.*, from 50 to 80 roentgen units or from 7.5 to 12.5 per cent skin erythema dose being given once a week over a period of six weeks. The one menstrual disorder which almost invariably fails to respond is hypomenorrhea (scanty flow) in regularly menstruating women. The cause of the menstrual deficiency in these patients is apparently within the uterus itself.

Surgical Treatment.—Lacerations of the vaginal wall and cervix, if present, should be corrected. In acute ante flexion of the uterus, dilatation and curettement, and occasionally the introduction of an intra-uterine pessary or drain, may do some good. Repeated dilatation of the cervix and curettage of the endocervical mucosa will probably cure some cases. Incision of the posterior lip of the cervix with removal of a small wedge of cervical tissue to facilitate drainage, may be helpful. Linear cauterization of the cervix is of value in chronic endocervicitis. Displacements of the uterus, if uncomplicated, should be corrected by manual or mechanical means. If complicated, operation should be resorted to. If benign tumors are present and thought to be responsible, these naturally should be removed.

If investigation reveals disorders within the pelvic cavity, especially in the fallopian tubes, the advisability of operation should be considered.

Uterosalingography is advisable only prior to contemplated operation. Fifty per cent neoskiodan in distilled water is employed as the radiopaque medium. If the uterine ends of the tubes are obstructed bilaterally, operation is hopeless. On the

other hand, if the fimbriated ends are obstructed, operation may be attempted.

However, tubal conditions are usually of an inflammatory nature, and, while tubal disorders may be overcome by re-opening the fimbriated ends, by attempting a restoration of the tubal canal, or by manufacturing new ostia (salpingostomy), the final results have been so unsatisfactory as to hardly justify the means. After salpingostomy in selected cases the tubes should be tested with gas or iodized oil at intervals to prove that they remain open. Gross inflammatory lesions of the tubes are usually permanent and from a practical standpoint functional restoration of these structures is impossible, and hence conception, following operation of whatever nature on these organs, is very improbable.

Surgery of the ovaries in which follicle cysts are ruptured may be of value.

Finally, one can hold out a hope for cure in sterile marriages in 50 per cent of cases where the tubes are patent and the male has some degree of fertility.

CONTRIBUTION BY DR. NORRIS W. VAUX

DIAGNOSTIC MISTAKES IN GYNECOLOGY

No one is more qualified to undertake writing an article dealing with the diagnostic mistakes in gynecology than I, and if there are any errors to which the human may fall heir, that I have not made, I would be extremely interested in knowing what they are. Experience is a hard teacher and one that leaves a vivid imprint of our errors, with their possible corrections, staring down at us from the walls and memories of the past. With this in mind, I shall briefly set down herewith a few words from my experience, which may help others to avoid some of the more common diagnostic errors by keeping before them the fundamental principles of the medical art. The usual diagnostic errors are ones in which, for the most part, the simple rudiments of physiology and anatomy and physical diagnosis are discarded for the more scientific and recent advances in laboratory technic and tests which have, it appears, taken their place in the practical and clinical experiences of others in large institutions and in teaching schools. Through the aid of the biological tests we are no longer dependent entirely upon the subjective and objective signs and symptoms of pregnancy to make our diagnosis. However, if one is mindful of the physiological changes occurring, and proceeds in making the diagnosis on the clinical findings established in the individual, it is seldom necessary to resort to the biological tests of Friedman-Lapham and Aschheim-Zondek. Pregnancy occurring in an individual who already has a complicated pelvic pathology such as ovarian cyst, myoma uteri, pelvic adhesions, etc., is frequently confused and the diagnosis of pregnancy often overlooked. It is in these

rather complicated diagnoses that we should be aided by the biological tests of pregnancy along with the clinical findings and diagnosis. The history of the individual such as abnormal amenorrhea which occurs occasionally in those suffering from endocrine deficiency, is seldom given the proper amount of importance. The whole problem of endocrinology can be held in close relation to the female pelvic organs and where the clinical history and study fails to throw light upon the individual problem confronted, a further and more intense endocrine study should be instituted. Although diagnostic errors are frequently made in determining the etiological factor of amenorrhea, a word of caution relative to the prolific use of endocrine substances to right this deficiency is timely. One should be opposed to the often widespread misuse of any or all of the endocrine substances, without first making a complete and careful clinical study with full laboratory analysis of the individual's blood to determine which of the endocrine substances, if any, is a possible potential factor needed in the individual case of amenorrhea. The cause of a large proportion of potential sterility cases lies in the failure of the endocrine substances to produce a normal premenstrual endometrium, which can at times be artificially produced. Certain individuals normal in all other respects, being mated with a fertile mate, will not become pregnant until a healthy premenstrual endometrium is present. In these cases it is essential, therefore, that a proper curettement and study of the endometrial tissue removed, be made before positive diagnosis of endocrine deficiency and lack of corpus luteum stimulation be given as the etiological factor.

Abortions and Miscarriages.—Diagnostic mistakes are common in this all too common interruption of early pregnancy. The diagnosis of pregnancy must be established first. As to whether the abortion or miscarriage is threatened or inevitable, remains to be determined on a clinical basis. A moderate amount of bleeding at the menstrual epoch does not always mean an inevitable abortion or miscarriage, but the passing of decidual tissue and embryological products deter-

mined by macroscopic and microscopic examination will differentiate between the threatened and the inevitable types. The more severe the bleeding and pain, the more guarded the prognosis should be and the more likely it is that the threatening termination will become inevitable. Excessive bleeding and uterine cramps with a moderate dilatation of the cervix and bulging of the lower uterine segment, place the case in the category of inevitable. Vaginal examinations are to be curtailed during the period of bleeding, as often this examination may add sufficient irritation to cause what is only threatening, to become inevitable. Intercourse during pregnancy, relatively near the menstrual epoch, is not given sufficient significance as a causative factor, and neglect in instructing the individuals to this effect is the physician's responsibility.

Ectopic Pregnancy and Pelvic Inflammatory Disease.

—The making of a differential diagnosis between ectopic pregnancy and pelvic or adnexal tumor masses is very difficult, and errors in establishing the correct conclusion are frequent. The history of previous infection is important, and if time permits, sedimentation test and a study of the clinical cause of the abnormality will help materially in reaching a diagnosis. The negative biological pregnancy tests as well as the leukocytosis which is present in the pelvic inflammatory cases, are of decided benefit. The adnexal masses associated with pelvic inflammatory disease are usually bilateral, while a bilateral tubal pregnancy is very rare. The pain and tenderness in the inflammatory cases is not as definitely localized as is the tenderness and local pain over the tube affected in ectopic pregnancy. On abdominal palpation the tenderness and rigidity in pelvic inflammatory disease is usually bilateral and lower abdominal, while in ectopic gestation this can only be elicited clinically when the tubal leak or rupture has taken place, with the subsequent increase in the peritoneal irritation and associated high leukocytosis which accompanies the presence of blood in the abdominal cavity. A posterior cul-de-sac puncture is advisable in all doubtful cases and is often helpful in making the diagnosis of tubal leak or rupture by the presence

of blood in the peritoneal cavity, while a cul-de-sac puncture free of blood would indicate more readily the presence of tubal and pelvic inflammatory disease. The diagnosis in carcinoma of the cervix has long been a frequent stumbling block of diagnostic error in this branch of gynecological practice. All cervixes should be carefully inspected as well as palpated, and the parametrial tissue and condition of the pelvic organs noted. The Schiller test and colposcopy examinations of erosions, ulcerations and eversions of the cervical mucosa and tissue are all to be looked upon with suspicion of malignancy until a further careful biopsy study is made of the removed tissue involved, which will either confirm or disprove your suspicion. The only positive method of diagnosing early malignant disease of the cervix is the careful pathological study of the removed tissue, which portion must include that area or areas of the cervix which are suspicious as to their appearance, and those areas which show definite reaction to the Schiller test. Endometrial scrapings which resemble malignancy are often erroneously diagnosed, and as this fatal complication can be completely arrested or cured in the early stages, drastic and intensive efforts should be made to prove or disprove the presence of early malignancy. No bleeding cervix should go undiagnosed or be allowed to continue with local applications alone. The immediate removal of the suspected tissue for study and diagnosis is the only correct method of preventing this diagnostic error. The diagnosis of malignancy cannot always be positively made without a thorough pathological study of the tissue, which study may have to be repeated, if the clinical manifestations persist. All examinations of the pelvic organs should be made wherever and whenever possible, with the bowels and bladder empty, preferably on a table in a proper gynecological lithotomy position, with sufficient light to justify a clear vision of the cervical and upper vaginal field. Neglect of this important procedure has frequently been responsible for inaccurate diagnoses of pelvic tumors and masses erroneously palpated and considered present. Cervical polyps should never be removed without includ-

ing their bases and a wide area of the surrounding tissue, and a complete pathological study made of the same. Polyps may be, or become malignant in character. Vaginal bleeding should not deter a proper gynecological examination. It is occasionally better and more advisable to have a clear conception of where the bleeding is coming from, and this can be accomplished only by visualization of the area. By no means should the examination be postponed indefinitely because of the bleeding alone. Every woman who has postmenopausal bleeding is a subject for complete and thorough investigation of first, the general systemic condition, and second, the pelvic organs, with malignancy always uppermost in our mind. If we postpone or neglect this important incipient stage, grave error is the result. Metrorrhagia is at times significant and diagnostic of some abnormality, the character of which is to be determined.

Malpositions of the Uterus.—The malpositions of the uterus are a source of much diagnostic controversy. The presence of uterine and adnexal malpositions is frequently confused with digestive, urinary and nervous conditions. Before a correct and accurate diagnosis can be made, the retroflexioversions, prolapse of the ovary, and acute antelexions must be corrected by manipulation or surgical procedure. The common complaint of patients with backache is never fully and completely gone into to the extent of determining the etiological factor, and errors in diagnosis result. The pelvic organs are frequently said to be the cause, when postural position, gastropptosis and allied genito-urinary and intestinal factors play the chief rôle in sacral and low lumbar irritability. Whenever possible, and always previous to the preparation of the patient for plastic and abdominal operation, the operator should make a complete check-up of his diagnosis with the patient under anesthesia, to avoid carrying out unnecessary and often harmful operative procedures. The recent work of Dr. Taylor on the influence of endocrine substances on a painful breast is timely and well considered, yet not any of the tumors of the breast, be they cystic adenoma

or malignant, should remain unstudied and untreated. Errors in diagnosis are common when a cystic mastitis is given as the diagnosis while malignancy exists in the tissue involved. Pathological examination of all tissues removed for diagnosis is timely and every tumor of the breast should be excised and carefully studied before a major procedure is undertaken. Neglected x-rays of the chest in suspected malignant tumors of the breast are frequently the cause of diagnostic errors in that metastasis can be noted in the lung tissue before symptoms are evidenced. No contemplated radical operation on the breast should be considered without a complete and thorough x-ray study of the mediastinal and pulmonary areas. Some of the painful breasts can be controlled well with a specific endocrine substance but the error lies in attempting to control the discomfort of the patient by the use of those simple, yet at times harmful hypodermic medications, while a malignancy is continuing its rapid proliferation into the adjacent glandular tissues and adjacent lymphatic structures.

Vaginal Discharges.—Probably more errors are made in diagnosing and treating vaginal discharge than all other gynecological complications. First, it is important to have the vaginal, cervical and urethral smears made from the discharge and these to be examined in the fresh state or in a hanging-drop as the presence of *trichomonas vaginalis* is frequently overlooked, if the fresh smear is not so examined. Other discharges must be stained and a routine search made in the specimen for the presence of *diplococcus* of Neisser, *streptococcus*, *bacillus* of Doederlein and significance for the treatment placed on the predominating organism found. Most of these conditions can be corrected; a large number cured; and a certain percentage remain unchanged after the proper treatment is instituted for each individual case. All ulcerations and erosions of the cervix and cervical canal must be treated by the cautery. On numerous occasions it will be necessary to remove the cervix and the cervical endometrium to completely arrest this distressing and common complaint in women. Too frequent douching is to be decried and it is desirable to

refrain from the use of too strong and irritating substances in the douch material. A cleansing alkaline douche, mild in type, will often give more satisfactory results. The patient should be instructed that the chronic types of leukorrheal discharge are difficult to cure and must persist in the treatment over a long period of time, to have a successful termination of the difficulties. Most of the irritating discharges will recur unless the positive etiology is determined and treatment directed toward its elimination.

Persistent Abortions and Miscarriages.—Persistent abortions and miscarriages are not uncommon in certain individuals and treatment can be directed toward the elimination of the abnormalities which may exist in the female organs of reproduction. Recently it has been determined by some investigators that a proportion of these individuals can be carried successfully to term by the use of "proluton." Distinct error is often brought about by the injudicious advice given individuals who are suffering from repeated disappointment due to this abnormality. The consequences are that the individuals themselves consider their case hopeless and their idea of a successful issue is abandoned. A word of caution will save serious error brought about occasionally by the injudicious cauterization of the cervix in child-bearing women. Conization and cauterization of the cervix are not procedures for the general practitioner and the reproduction of the individual must not be lost track of, as improperly performed cauterization will cause cicatricial stenosis of the cervix which may ultimately result in dystocia in the first stage of labor. It is further to be cautioned that an extensive conization of the cervix is not to be considered as a dispensary or an office practice, for the reason that severe hemorrhage can, and will follow such procedure if the patient is not kept in bed under observation for a forty-eight-hour period following this extensive procedure.

CLINIC OF DR. FRANKLIN L. PAYNE

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA

THE CAUSES OF ABNORMAL VAGINAL BLEEDING DURING THE PRE- AND POSTMENOPAUSAL AGES

THE menstrual lives of woman may be divided into four periods, each of which is accompanied by characteristic peculiarities of menstruation and by more or less characteristic pathologic conditions which result in abnormal bleeding. During the adolescent period, while the rhythm of the cycle is being established, disturbances in endocrine function give rise to most of the menstrual abnormalities. The child-bearing period is accompanied occasionally by dysfunctional bleeding, but those conditions which result from sex lives, genital infections and abnormalities of pregnancy, predominate as the causes of abnormal bleeding. In the premenopausal age, gradual recession of ovarian function is attended frequently by functional menstrual disturbances, but doubly as frequent are the neoplastic diseases, both benign and malignant, which characteristically appear at this time. During the postmenopausal era any vaginal bleeding is pathological in origin. Such bleeding usually depends upon local atrophic changes incident to the menopause or follows the development of neoplastic disease.

The study of irregular pre- and postmenopausal bleeding is particularly important because of the frequency with which malignancy occurs during these ages. The menopause theoretically is that point at which ovarian function ceases and permanent amenorrhea appears. Clinically, however, it is often impossible to designate such a point. The average age of the

menopause was found by Dr. Charles C. Norris to be forty-seven and one-half years (Fig. 1). The age limits extended from forty to fifty-five years, with a gradual rise in incidence from forty to forty-eight years, and a sharp decline after forty-eight years.

The length of the premenopausal era ranges from a few months to several years, during which time irregularities of menstruation frequently occur. It is often difficult to interpret correctly these irregularities because of the wide variations both in interval and in character of the flow which commonly

Fig. 1.—(Norris in *International Clinics*, vol. I, Series 45. J. B. Lippincott Co., Publishers.)

accompany the normal change of life. While they usually indicate simple functional disturbances, the possibility of more serious conditions should always be borne in mind. Particularly is this true in the event of bleeding between the regular menstrual periods.

Many of the figures in this article are based upon a study of 2000 patients forty years of age or over which has been reported by Dr. Floyd E. Keene elsewhere, to whom the author is grateful for permission to use his statistics. The patients are divided into the premenopausal group of 1398 patients and the postmenopausal group of 602.

Premenopausal Bleeding.—The conditions which resulted in abnormal bleeding during this period were benign in practically 86 per cent of the cases and in the remaining 14 per cent malignant disease was responsible (Table I). The

TABLE I

locations of the lesions are interesting when the benign and malignant conditions are contrasted. Over 90 per cent of the benign conditions occurred in the upper genital tract, while 80 per cent of the malignant diseases were found in the lower tract. Cervical cancer accounted for more than 75 per cent of the malignant bleeding, and less than 6 per cent of the benign bleeding could be attributed to cervical conditions. While fundal malignancy is usually a postmenopausal condition, the 15 per cent incidence here recorded shows that it should always be considered in the absence of other obvious lesions to account for irregular bleeding.

Of the benign conditions which caused abnormal premenopausal bleeding, tumors made up two thirds of the group (Table II). Uterine myomata were by far the most fre-

quent and they comprised over 60 per cent of all the benign lesions. Endometrial and cervical polyps were moderately common and ovarian tumors accounted for a small number. Ovarian dysfunction caused one fourth of the irregularities. Functional menstrual disturbances are most likely to occur at this age. In a recent study of functional uterine hemorrhage, we found that one half of the cases fell between the ages of forty and fifty years. The progressive ovarian changes which eventuate in the menopause, frequently result in abnormal secretion, distorted endometrial stimulation and irregular bleeding. In many instances such irregularities do not cause concern unless excessive blood loss results. The occurrence of bleeding between the menstrual periods, however, should always suggest the possibility of malignant disease. Genital infections and complications of pregnancy play a very small rôle during the premenopause. The inflammatory group in Table II is composed of vaginal ulcers, cervicitis and cervical erosions with infection, as well as adnexal inflammatory lesions. Pelvic inflammatory disease contributed less than 2 per cent of the causes of benign irregular bleeding in this study. Benign cervical lesions likewise accounted for less than 2 per cent of the abnormal bleeding. The fact that this study was based upon hospital patients may produce a distorted picture of the true incidence of bleeding benign cervical erosions. Yet we cannot escape the conclusion that, as Dr. Keene puts it, "in a woman of the menopausal age an erosion of the cervix which bleeds is often malignant." The curability of cervical cancer is inversely proportionate to the stage of its extension, and early diagnosis is certainly the most important factor in its successful management. Because of its location in an area which is practically devoid of sensory nerve fibers, pain does not occur until the growth has become hopelessly advanced. The most frequent symptom of early cervical cancer is irregular vaginal spotting from an area which bleeds following trauma.

Among the recently proposed methods of rapid diagnosis of cervical malignancy are the Schiller test and the use of the

colposcope. The Schiller test is based upon the fact that malignant cells, because of the lack of glycogen, do not take the iodine stain. While we have found this procedure to be valuable in locating questionable lesions for the purpose of biopsy, it does not enable final diagnosis. Our experience with the colposcope has not induced us to employ it to the exclusion of the final and most important diagnostic procedure: biopsy of the suspicious areas and microscopic study of stained sections by one who has been trained in gynecologic pathology. This examination is indicated in the presence of any cervical erosion occurring during the premenopausal age, which bleeds upon trauma.

Approximately three fourths of the menstrual irregularities of the premenopause arise from either the cervix or the body of the uterus. Comparison of the relative incidence of benign and malignant lesions in the two sites shows that over 65 per cent of the cervical and less than 4 per cent of the fundal lesions were malignant (Table III). Abnormal premenopausal

bleeding of cervical origin is usually due to cancer, while similar fundal bleeding is usually benign in origin. The fact that 4 per cent of the fundal lesions were malignant, emphasizes the importance of careful investigation of the endometrial cavity. Most of the cases of unsuspected fundal cancer which have been found in our laboratory occurred in association with myomata. Approximately 1 per cent of the myomata undergo sarcomatous degeneration. Adenomyomata in rare instances became carcinomatous. A greater possibility is that an endometrial cancer may be masked by the presence of a myoma. The characteristic menstrual abnormality of the uncomplicated uterine myoma is menorrhagia (profuse or prolonged bleeding

at the regular menstrual time). In the event of metrorrhagia (intermenstrual bleeding), the existence of some complicating condition, such as a pedunculated, submucous tumor, endometrial polyps, benign or malignant degeneration of a myoma, or a malignant endometrial change should always be suspected.

Postmenopausal Bleeding.—Because of the great difficulty in determining accurately the exact time of the menopause, no patient was included in the postmenopausal group unless a year or more had elapsed between the last menstrual period and the development of irregular bleeding. The menopause is accompanied by changes in physiology and in the pelvic structures, which alter the types of conditions responsible for vaginal bleeding. During the premenopause, a considerable proportion of the menstrual abnormalities, both in the presence of myomata and otherwise, result from disturbances in ovarian function. On the other hand, postmenopausal bleeding usually follows some form of degeneration, either benign or malignant. In fact its occurrence is due to malignancy in approximately 60 per cent of the cases (Table IV).

TABLE IV
POSTMENOPAUSAL HEMORRHIAGE
Incidence of Malignant Causes

<i>Author</i>	<i>No. Pts.</i>	<i>Malignancy</i>

Geist and Matus	190	58.0 " "
C. C. Norris	189	52.9 " "
Total	1443	60.7 per cent

In the series reported by Dr. Keene, benign lesions accounted for only 38 per cent of the postmenopausal bleeding (Table V). These nonmalignant lesions were situated in the lower genital tract in more than three fourths of the cases. The atrophic uterus accounted for about 15 per cent of the benign postmenopausal bleeding, against the overwhelming preponderance of 65 per cent which is seen in the premenopause. On

the other hand, the uterine fundus housed 40 per cent of the malignant conditions causing postmenopausal bleeding, most of which were fundal cancer. It is interesting to note that even after the menopause, cervical malignancy is much more frequent than malignancy of the fundus.

The benign lesions which resulted in postmenopausal bleeding were neoplastic in only 40 per cent of the cases (Table VI). These lesions consisted of endometrial or cervical

TABLE VI

Trauma	27.5 " "
Unexplained	2.6 " "

polyps, myomata and a small number of ovarian cysts. Polyps cause postmenopausal bleeding far more frequently than do myomata. The postmenopausal fibroid is a heritage from the menstrual era, and bleeding from this source usually indicates benign or malignant degeneration of the tumor or an associated malignancy either in the endometrium or adnexa.

The atrophic genital changes incident to the cessation of ovarian function form the basis for almost all the remaining benign postmenopausal bleeding. The thinned out ischemic tissues of the lower genital tract are particularly susceptible to nonspecific infection and to trauma. Senile vaginitis is com-

monly accompanied by multiple small areas of ecchymosis which cause irregular spotting. The postmenopausal prolapsed urethral mucous membrane often bleeds on trauma. The atrophic cervix occasionally presents a bleeding erosion. Frequent causes of spotting are the cervical and vaginal ulcers which accompany varying degrees of postmenopausal uterine prolapsus.

Therefore, trauma and infection, or a combination of the two, accounts for approximately 60 per cent of the benign postmenopausal bleeding. The bleeding which accompanies these conditions is usually scanty, often no more than blood-stained leukorrhea. The importance of these lesions lies in the fact that they may mask the presence of more serious trouble. The character of the discharge or bleeding and the duration of symptoms often aid in the decision as to the necessity for thorough investigation. If the examination can be made at the time of bleeding, the origin of the blood is usually determined. Any postmenopausal bleeding from the uterine fundus, either spontaneous or following trauma of the endometrium with the sterile sound, indicates an immediate diagnostic curettage. In the absence of this posttraumatic uterine bleeding and in the presence of an obvious cause for the spotting in the lower genital canal, as vaginitis, cervical polyps, etc., it is generally safe to treat these conditions and to keep the patient under careful observation for at least a year. Should the bleeding persist after the obvious lesions are cleared up, or should it recur, the endometrial cavity must be investigated at once. A small area of uterine malignancy may escape even a thorough curettage. Pemberton recently reported 6 cases of fundal carcinoma, from a group of 923 patients, which developed in such a short time after the curettage that he believes they were missed by the curet. We have not had a similar experience but in approximately 3 per cent of our postmenopausal hemorrhages, thorough examination including curettage under anesthesia has not revealed the cause of the bleeding. Postmenopausal rejuvenation occasionally occurs, with the appearance of pseudomenstruation. At times no

reason is found, and occasionally it is the result of ovarian cancer. Particularly is this true of granulosa cell tumors of the ovary, which secrete estrin and stimulate endometrial changes similar to those found in many instances of dysfunctional uterine bleeding of the menstrual era.

TABLE VII

POSTMENOPAUSAL HEMORRHAGE

Relative Incidence of Benign and Malignant Uterine Lesions

	<i>Benign</i>	<i>Malignant</i>
Cervix	40.8 per cent	59.2 per cent
Body	21.1 " "	78.9 " "

The uterine cervix and the fundus proved to be the cause of bleeding in approximately 80 per cent of all the cases of postmenopausal hemorrhage. Of the cervical lesions, 40 per cent were not malignant and consisted mostly of benign polyps and those conditions resulting from postmenopausal atrophy plus trauma or infection (Table VII). Of the fundal lesions or when the blood was found to be coming down through a normal cervix, almost 80 per cent of the bleeding was of malignant origin, usually carcinomatous. Given a normal cervix in a woman past the menopause, uterine bleeding usually means cancer.

For the purpose of emphasis, certain salient points are listed below:

Premenopausal abnormal bleeding is malignant in origin one out of six times, while postmenopausal bleeding is malignant four out of six times.

Premenopausal cervical bleeding, in hospital cases, is malignant two out of three times, and premenopausal fundal bleeding is malignant one out of twenty times.

Postmenopausal cervical bleeding is malignant three out of five times, while postmenopausal fundal bleeding is malignant four out of five times.

Premenopausal menorrhagia is usually benign in origin, but metrorrhagia at this age is always suggestive of malignancy.

Postmenopausal bleeding in most instances arises from degenerative lesions, 60 per cent of which are malignant.

CLINIC OF DR. MARGARET CASTEX STURGIS

WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA

TREATMENT OF HABITUAL ABORTION

HABITUAL abortion is a term used to apply to repeated or recurrent abortions in which there appears to be no recognizable cause. Therefore, herein will be considered only those repeated abortions which do not follow the more commonly accepted causes, as infections (lues the most common), abnormal endometrium, decidua and placenta, fibroid growth in the uterus, malpositions, trauma, or defective germ plasm (which may be endocrine).

The problem of habitual abortions is believed by most gynecologists today to be related to an endocrine imbalance, although there is a group who still believe the cause to be hypovitaminosis. The impetus in recent years given to research in sterility studies and endocrinology has added much to the knowledge of the endocrine factor in pregnancy and its premature termination. Habitual abortion therefore has been removed from that discouraging place in medicine allotted to abortion of habit and has been given a very deserving recognition in the study and treatment for relative sterility.

Certain physiological effects of the corpus luteum on the genital tract have been demonstrated and are now accepted. In 1903 Fraenkel¹ proved that the removal of the corpus luteum of early pregnancy in rabbits resulted in the termination of the pregnancy. An interrelationship has likewise been established between the luteal hormone and the fertilized ovum during the early months of pregnancy. Weichert,² Allen³ and others have demonstrated that progestin, the lutein hormone,

does prepare the endometrium for the fertilized ovum and Hisaw⁴ has shown that it exerts an inhibitory influence on the muscular contractions of the uterus. Its ability to inhibit pituitrin has likewise been demonstrated. Other observers have shown that the corpus luteum is necessary for the early months of gestation. Estrin and progesterin are apparently antagonistic in their action upon the uterine musculature.

As a result, the facts have led to the theory that while the corpus luteum is in ascendancy the pregnancy continues, because pituitrin and estrin are inhibited. If estrin becomes dominant the uterus is sensitized to pituitrin and labor ensues.

As early as 1913 Seitz⁵ suggested the corpus luteum as the cause for pathologic changes in habitual abortions. In 1919 J. C. Hirst⁶ used an aqueous extract of corpora lutea obtained from pregnant cattle in attempting to prevent abortions. Hofbauer,⁷ Halban,⁸ Glismann,⁹ Schwarz,¹⁰ Kunz,¹¹ Mazer and Goldstein,¹² Wells,¹³ Hall,¹⁴ Bishop¹⁵ and others have treated habitual abortions with some preparations of progesterin. Witherspoon¹⁶ has used the anterior pituitary luteinizing hormone in abortions with such satisfactory results and suggests the use prophylactically in cases of habitual abortion, follutein was used. Sellheim¹⁷ used the blood serum from normal, healthy pregnant women to treat nine patients who had previously aborted two or three times between the third and fourth months. He used 10 cc. of blood serum every two weeks with satisfactory results.

An indirect endocrine imbalance is apparently due to thyroid deficiency. Roffo,¹⁸ Bland,¹⁹ von der Hoeven,²⁰ LeLorier²¹ and M. Mayer and others believe that thyroid deficiency is responsible for sterility and if pregnancy ensues will cause abortion in later months if not treated. They report excellent results on thyroid therapy in those cases showing deficiency prior to pregnancy and in those cases especially which abort in the late months of pregnancy.

Carbohydrate metabolic imbalance either existing before as diabetes or during pregnancy has been treated by low

carbohydrate diet and insulin with success. Williams²² in a series of 19 cases found a very low sugar tolerance and advised reduction of total carbohydrate intake, about 150–200 Gm. a day, taken in small rations at more frequent intervals. In 2 cases he used insulin.

Hypovitaminosis must be considered. Much has been written on deficiency in vitamin E in sterility and in causing habitual abortions. Vogt-Möller²³ has probably contributed more than any other on the use of wheat germ oil or wheat germ in treatment of abortions. He suggests that the vitamin E content of an ordinary diet is difficult to estimate and, too, that some women require more than the ordinary amount of vitamin E. He also believes that a hypovitaminic state exists during pregnancy caused by the increase in the maternal metabolism and vitamin requirement of the fetus. He further asserts that this may reflect back to the thyroid imbalance, dental caries, anemia, neuritis, etc. Since wheat germ oil is entirely harmless he believes all cases should be treated with it. He gives 5 cc. wheat germ oil daily by hypodermic, in early pregnancy, for two weeks, and gradually decreases to 5 cc. every six days until the patient has passed the time for the abortion to occur.

Treatment.—Habitual abortions appear to be explained physiologically and since the causes relate to a disturbance of the secretion of the ovarian hormones, treatment lies in the adjustment of the quantitative relation of estrin and progestin. The therapy, therefore, is prophylactic and consists in general or constitutional and specific or endocrine treatments.

Constitutional.—*Tonic.*—The same general tonic treatment necessary in all prenatal cases is especially required. Attention should be given to the intake of cod liver oil, calcium, iron, etc.

Dietetic.—A well-balanced diet with preponderance of green vegetables and fruits, together with 1 quart of milk daily must be assured. Variations are applicable for individual indications as in other prenatal cases. Carbohydrate metabolism must be watched, using blood sugar estimations

to control carbohydrate intake. Experimentally, deficiency in vitamin E has been responsible for repeated abortions but this has not been proved the case with humans. However, it must be borne in mind in cases not responding to other treatment.

Sedative.—Rest has proved in my experience a very helpful method in preventing termination of pregnancy prematurely. At the time of the menstrual date the patient is kept in bed for two days prior and during the time corresponding to the usual menstruation period. Coitus is forbidden at any time. No automobile rides at any time. Strenuous activity of all kinds is removed. If there are no threatening symptoms, walking is the one exercise approved. Keep bowels moving normally with mineral oil and laxative foods, avoiding laxative drugs in order to maintain a physiological rest of the intestinal tract. In some cases sedation is necessary; using bromides, opiates are reserved for cases showing symptoms of abortion.

Endocrine Treatment.—*Substitutive.*—Without doubt, the best results are obtained in the prevention of habitual abortions in the early months by the use of corpus luteum (progestin). One cc. ampule containing 1 rabbit unit of luteum hormone should be given two or three times a week, intramuscularly until the fetus is viable. Some clinicians give it only during early months. Krohn²⁴ gives the medication until after the thirty-second week and permits his patients to be ambulatory unless abortion symptoms arise.

Stimulative.—The increased functional activity of the thyroid during pregnancy is a known observation and it is logical to assume that it does participate in the changes taking place within the uterine mucosa of pregnancy. There are those cases in which the thyroid seems unable to meet the demands. It is in these cases that thyroid glandular extract is indicated. The dosage should be regulated by the pulse rate and basal metabolic rate. There are clinicians who recommend its use even without apparent cause. Bland¹⁹ employs 1½ grains daily for one week, alternating with 10 grains

sodium iodide. Mazer¹² gives 2 ampules of corpus luteum extract subcutaneously every other day for the first twenty days of each month until the fetus is viable. He also gives $\frac{1}{2}$ grain desiccated thyroid for two weeks and 4 grains of sodium iodide the other two weeks, alternating during this same period.

There is much contradictory evidence concerning the results from the use of the anterior pituitary sex hormone in treatment of habitual abortion. My own experience does not warrant the use because, although theoretically it stimulates the corpus luteum, it likewise stimulates the production of estrin, which is antagonistic to pregnancy. The author has had no experience with blood serum but feels that the same objection applies.

Summary.—Substitutional treatment with the lutein hormone appears to be the logical and clinically proved effective treatment for habitual abortions. The use of thyroid medication alternating with iodides has been clinically valuable especially in cases showing thyroid deficiency and in those cases aborting in the latter months of pregnancy. Active endocrine therapy must be used prophylactically and not discontinued even when abortion is threatened until the fetus is definitely no longer viable. Tonic, dietetic and sedative measures are additional adjuncts and are not to be overlooked because, in the author's experience, meticulous attention to minor details have in her opinion made possible many good results.

CLINIC OF DR. AARON CAPPER

JEFFERSON HOSPITAL

THE DIAGNOSIS AND TREATMENT OF CYANOSIS OF THE NEWBORN

Introductory Remarks.—In discussing cyanosis of the newborn, one must include as well, for the sake of completeness, a discussion of asphyxia of the newborn. The latter condition is the broader concept and includes as its etiologic agent or agents, many of the causes of cyanosis. The pathologic changes that are present in the blood of cyanotic infants are also a predominant feature of asphyxia. Most cases of asphyxia neonatorum exhibit cyanosis as one of the signs. The term "asphyxia" is usually employed to describe that condition in which spontaneous respiration is not established with sufficient promptness or force to maintain life. It follows, therefore, that when respiration is established, asphyxia no longer exists. Cyanosis, however, may and does continue for many hours, days, weeks, months and even years after normal respiration has been instituted.

The placenta is the medium through which fetal respiration is carried on in utero. It is through this organ that oxygen is received and carbon dioxide carried off. When the placental circulation is suddenly interrupted, the supply of oxygen is suddenly cut off and carbon dioxide accumulates in the blood. It is presumed that as a result of the accumulation of carbon dioxide, an increase in the hydrogen ion concentration of the blood develops, which, in turn, is the initial stimulus to the respiratory center. The greatest immediate danger which the

newborn encounters on its way into the world, is the interruption of its intra-uterine respiratory mechanism. Every baby is, as a rule, born with some degree of asphyxia. This is produced in utero by the uterine contractions, which retard somewhat the placental circulation, thus entailing an increase in carbon dioxide and a decrease of oxygen in the fetal blood. A further intensifying of the already dangerous state is produced by the pressure on the advancing head of the fetus on the pelvic floor, which causes a still greater slowing down of the fetal circulation and hence a decrease in the oxygen content of the tissues. Any factor, therefore, which interferes with placental circulation may produce some degree of asphyxia. The most important of the causes are usually:

1. Prolonged second stage of labor. The likelihood of intra-uterine asphyxia is greater than a direct proportional relationship to the duration of labor, particularly of the second stage. Statistics show that the mortality from asphyxia after a second stage of labor of four hours or more was over three times as great as when it lasted but one hour.

2. The injudicious use of pituitrin.

3. Maternal convulsions.

4. Narcotization, particularly from morphine or nembutal.

5. Breech presentation with difficulty in delivering the after-coming head.

6. Prolapsed cord, pressure on the cord or its wrapping around the neck.

7. Early separation or low implantation of the placenta.

These conditions may cause a cerebral anemia and consequent failure of the respiratory center to function, thus leading to asphyxia or its milder state, cyanosis.

Definition.—What is cyanosis? Cyanosis is a bluish discoloration or tinge of the skin and mucous membranes, best observed on the lips, ear lobes and nail beds and, if fairly severe, on any part of the skin or mucous surface. This blueness is caused by an increased amount of reduced hemoglobin in the capillaries of the skin and the mucous membranes. Otherwise expressed, cyanosis develops clinically when a suffi-

cient amount of oxygen unsaturation develops in the blood. Oxygen unsaturation is that value which results when the actual oxygen content of the hemoglobin is subtracted from the oxygen capacity, or it is the difference between the oxygen capacity of the hemoglobin and the actual oxygen carried by it. An oxygen unsaturation of the capillary blood above 6.5 volumes per cent is considered the threshold for the appearance of cyanosis.

Types or Degrees of Cyanosis.—Of course, in discussing cyanosis of the newborn, one usually has in mind the generalized form in which the whole skin and mucous membranes appear to be bluish, the depth of the discoloration depending upon the degree of the underlying cause. Often cyanosis is visibly limited only to the lips and nail beds; sometimes it is only circumoral, and then it is usually in its mildest form. Localized cyanosis of one half or only a part of the body of the newborn is usually the result of pressure or constriction of that part during delivery. On the other hand, Smith¹ recently reported three cases of transient localized cyanosis of the newborn following spontaneous delivery, in two of which the face and anterior scalp were involved, and in the third, the head, neck, arms and upper thorax were affected. The cyanosis cleared in all three within five days. In these cases, the author intimated that the cyanosis was undoubtedly the result of interference with free venous drainage of the involved area, due possibly to some vasomotor disturbance of the veins.

Cyanosis is much more common in premature and immature infants, the incidence being at least 50 per cent. Clein,² on the basis of postmortem follow-up studies of premature infants, classifies cyanosis into continuous, intermittent, terminal and spontaneous or occasional. The continuous form was present from birth to the time of death and was found to be associated with marked atelectasis of the lungs. Intermittent cyanosis was caused mainly by cerebral hemorrhage, chiefly of the infratentorial type; those infants who died between the tenth and twenty-seventh days of life also had an associated infection. Terminal cyanosis, as the name implies, was pres-

ent a few hours to a day or two before death, and was usually a terminal event in such severe infections as otitis, mastoiditis, pneumonia, tuberculosis or syphilis. Sporadic or occasional cyanosis was seen in a case of congenital heart disease. We do know, however, that occasional cyanosis is not necessarily limited to that cause; on the contrary, congenital heart disease, if it is of the cyanotic type, generally causes continuous cyanosis. Occasionally cyanosis is sometimes encountered in both premature as well as full-term infants, following a vomiting spell, during coughing, gagging, choking and sometimes during feeding.

Causes of Cyanosis.—There is quite a variety of pathologic conditions operative in the production of cyanosis of the newborn. Some are mild and easily preventable, others are serious and beyond help. In a general way the causes may be classified as:

1. Those associated with delivery, and the most common are:
 - (a) Aspiration of foreign material.
 - (b) Prolonged and difficult labor.
 - (c) Early placental separation.
 - (d) Cord displacements.
 - (e) Narcotization.
 - (f) Severe circulatory or toxic conditions of the mother.
2. Traumatic conditions of the infant:
 - (a) Cerebral edema.
 - (b) Cerebral hemorrhage.
 - (c) Injury to the phrenic nerve.
3. Developmental anomalies of the infant:
 - (a) Congenital heart disease.
 - (b) Atelectasis of the lungs.
 - (c) Enlarged thymus gland.
 - (d) Diaphragmatic hernia.
 - (e) Prematurity.
 - (f) Micrognathia, leading to tongue swallowing.

4. Infectious states of the infant:

- (a) Pneumonia or less serious respiratory infections.
- (b) Sepsis.

5. Metabolic disturbances, especially tetany of the newborn.

While the above list does not exhaust all the possible causes of cyanosis of the newborn, nevertheless, it is believed to account for the great majority of cases in which cyanosis is either the chief symptom or is an important contributory finding. It is most important to bear in mind the possibility of the existence of more than one causative factor in any given case; for instance, a baby that is born with the cord wrapped about its neck may also be the victim of a defect in the heart; an infant with intracranial birth injury may, and frequently does, have an associated atelectasis of the lungs; intracerebral hemorrhage is quite common in premature infants. It is, therefore, incumbent upon the physician not to rest content with the mere finding of one, or even two, distinct pathologic entities, as a possible explanation of the cyanosis, but to thoroughly investigate and study each baby and attempt to exclude every known cause for cyanosis in the course of his differential diagnosis.

Modus Operandi.—Some of the pathologic states act directly upon the respiratory center, others interfere with the proper exchange of gases in the lungs; some interfere with the proper entry of air into the lungs, while others do their damage in the circulatory system. The simplest condition is the mechanical obstruction of the larynx and trachea by aspirated foreign material. It is conceivable that, as a result of the increased venosity of the fetal blood, the respiratory center may even be stimulated before birth, thus leading to aspiration of mucus, etc. More commonly, the baby's first gasp is initiated by the sudden change from the intra-uterine warmth to the cool atmospheric temperature; in breech deliveries, the head is still in the birth canal while the body has already been subjected to the stimulation of the room temperature. Whatever material may be near or within the baby's mouth, can

be aspirated into the pharynx, larynx, trachea or bronchi. Hence, obstruction of the upper respiratory passages may be due to vaginal mucus, feces, amniotic fluid, blood or meconium. This foreign material interferes with the entrance of air, and hence oxygen, into the pulmonary area to carry on proper respiration.

Prolonged and difficult labor, prolapsed cord, undue pressure upon the cord, low implantation of the placenta or its too early separation, and maternal convulsions, all act more or less in the same manner to bring about cyanosis. They cause cerebral anemia and consequent failure of the respiratory center to function. They interfere with the proper exchange of gases, leading to a disturbed carbon dioxide-oxygen relationship in the fetal blood, for cyanosis may be due either to increased carbon dioxide, or diminished oxygen, or a decreased carbon dioxide and oxygen content of the blood.

Narcotization by too large a dose of nembutal and its derivatives or by too much morphine or by morphine administered between four hours to a half hour before delivery, may interfere greatly with initiation and continuation of respiration. These sedatives apparently have too depressing an effect upon the fetal respiratory center. DeLee³ says that "morphine must be given at such time that the fetus will have recovered from its effects before it is born, or at a moment when we are certain the drug will not have passed over to the child in any considerable quantity by the time that it is delivered; morphine may be given up to four hours before birth, but not from then on until thirty minutes before delivery." Dunham⁴ found that in a group of mothers in whom there was no history of any condition other than the administration of morphine, which of itself as far as could be determined might account for delay in respiration of the infants, when compared with a similar group of mothers who had no morphine, there was a delay in respiration in 15 per cent of the infants born to the former group, whereas in the mothers who had no morphine before delivery, only 4 per cent of the infants suffered with delayed respiration.

In cerebral edema as well as hemorrhage, the respiratory center is depressed in its activity and hence there is a lack of the normal amount of carbon dioxide which is the necessary stimulus. If the hemorrhage is supratentorial, the increased intracranial pressure is more equally divided; however, in infratentorial hemorrhages, there is greater pressure on the basal structures of the brain, resulting in greater cyanosis. Hunt,⁵ whose investigation is based upon 600 consecutive autopsies performed upon infants who died at the New York Nursery and Child's Hospital over a period of five years, selected 118 patients whose death occurred before one month of age and who showed definite cyanosis of more than a transient nature. Injury to the brain or meninges was found more frequently than either pulmonary involvement or cardiac anomalies. Occasionally, cerebral hemorrhage and atelectasis coexisted and the latter was secondarily the result of the hemorrhage. Cerebral trauma depresses the respiratory center sufficiently to interfere with proper respiration and alveolar opening. As a result of this atelectasis a secondary pneumonia may result. Hunt⁵ in his series of 118 autopsies found only four cases of severe atelectasis, but in each instance there was also a large cerebral hemorrhage, which was probably the primary lesion. It must be borne in mind, however, that this great proportion of cases of intracranial hemorrhage as a cause of cyanosis were all fatal ones. Fortunately, the greater majority of infants suffering from neonatal cyanosis do not have an unfavorable outcome and they must therefore have a less serious pathologic condition underlying the cyanosis.

Phrenic nerve injury, if present, is usually associated with brachial palsy. If the latter condition, therefore, is associated with cyanosis, one must consider an injury to the phrenic nerve, which is made up of the fourth and fifth cervical spinal nerves, and hence a part of the brachial plexus. Injury to that nerve causes interference with diaphragmatic action and hence disturbed respiration and cyanosis.

Not all cases of congenital cardiac anomalies cause cyanosis; in fact many of them are never associated with cyanosis.

The congenital heart diseases may be divided into the cyanotic group (venous-arterial shunt) and the noncyanotic group (arterial-venous shunt). For our purposes it will suffice if we consider only the former group. Abbott⁶ says: "The dependence of congenital cyanosis upon deficient oxygenation is now definitely established; that the circulation evidently accommodates itself to a certain degree of oxygen unsaturation, whether brought about by obstruction in the course of the pulmonary artery, by a general retardation of flow, or by a mingling of venous with arterial blood, but that as soon as deficient oxygenation reaches a certain limit, this becomes insufficient for the needs of the body and cyanosis results.

"Cyanotic Group (*Morbus coeruleus*).

"1. Cases of venous shunt (arranged in order of severity of shunt).

"(a) Moderate cyanosis. Dextroposition of aorta with defect at base of ventricular septum; complete absence of ventricular septum; pulmonary stenosis of inflammatory type with closed ventricular septum and patent foramen ovale; tricuspid atresia with interauricular septal defect and transposition of the great trunks.

"(b) Marked cyanosis. Pulmonary stenosis with dextroposition of aorta and interventricular septal defect (tetralogy of Fallot); pulmonary atresia with ventricular septal defect, dextroposition of the aorta, and patent ductus; transposition of arterial trunks with ventricular septal defect and dextroposition of the aorta.

"(c) Extreme cyanosis: Complete absence of cardiac septa (*cor biloculare*); complete defect of aortic septum (*persistent truncus*); transposition of arterial trunks with patent foramen ovale and patent ductus but closed interventricular septum; pulmonary atresia with closed ventricular septum, patent foramen ovale and patent ductus; aortic and mitral atresia with defect of interventricular septum and aplasia of aorta."

Pulmonary atelectasis has been given entirely too much prominence as an etiologic agent in cyanosis or asphyxia of the newborn, particularly in full-term infants. As a disease

entity *per se*, it is clinically found much less frequently and discovered at autopsy still more rarely. It is supposed to cause cyanosis by its interference with the entrance and exchange of gases in the alveolar spaces. According to Loewy and von Schrotter,⁷ two thirds of one lung may be rendered useless by bronchial obstruction before cyanosis appears. Hunt,⁵ concludes, as a result of his autopsy studies of the 118 newborn babies with cyanosis mentioned above, that "it was not possible in any instance to demonstrate sufficient pulmonary atelectasis to warrant the assumption that it was the sole cause of the cyanosis." It is now well known that a certain amount of atelectasis is present in all newborn infants, and with age, crying and breathing, the atelectasis clears. All the alveoli in the lungs are not opened up with the first gasp; it takes days or even weeks before the entire lung surface is unfolded; for this reason a certain amount of atelectasis may almost be spoken of as physiologic. In premature infants particularly there is not only a certain degree of this type of atelectasis, but there are also areas of undeveloped lung tissue which, it is presumed, in time grow into normal alveolar structures. It is probably on this account that cyanosis is so much more common and more severe in the premature.

It is now generally conceded that the rôle of an enlarged thymus gland as a cause of asphyxia and cyanosis in the newborn has been overestimated. The author,⁸ in a study of 1074 newborn infants for enlarged thymus, found the gland to play a practically negligible, if any, rôle, in the causation of cyanosis. The cases, in which the roentgenologist reported an enlarged thymus with encroachment upon trachea, were found at autopsy to suffer with either cerebral hemorrhage or pneumonia as a cause of the symptoms.

Diaphragmatic hernia, although rare as a cause of cyanosis, will, if present, contribute to the symptom through the encroachment of the abdominal viscera upon the thoracic cavity and displace lung tissue as well as the heart.

Prematurity, as we mentioned elsewhere, is a most common cause of cyanosis. There are several reasons for this oc-

currence. In the first place, the respiratory center is only partially developed; this makes it less susceptible to carbon dioxide stimulation. The above-mentioned undeveloped lung tissue is another important factor. The premature and immature infant is much more susceptible to intracranial edema or cerebral hemorrhage thus increasing the cyanosis. Finally, sepsis, and particularly pneumonia, is more often a complication of prematurity than of full-term infants, thus enhancing the cyanotic tendency.

Hypoplasia of the mandible (micrognathy) causes cyanosis by the tendency to tongue swallowing. As a result of the short mandible, the tongue is displaced backward, and acts as a simple mechanical factor in obstructing the air flow.

Respiratory infections cause congestion of the bronchi and alveoli and interfere with the proper exchange of gases. These infections as well as other septic infections may by their fever and toxins also act upon the respiratory center in a deleterious manner.

Of late, it has been recognized that some convulsions of the newborn may be due to tetany, a metabolic disturbance. Not only may this condition be responsible for convulsive seizures, but as a result of the laryngo- or bronchospasm, less air enters the alveoli and air hunger resulting in oxygen unsaturation and cyanosis may result.

Diagnosis of Cause of Cyanosis.—As in every other branch of medicine, a thorough history of the case yields invaluable information to aid in the proper diagnosis. Here, the obstetrician rather than the parent is called upon to give the desired data, particularly when it is suspected that the cause of cyanosis might be an accident of labor. Was the mother in good health or did she suffer from some chronic or debilitating ailment in the last months of her pregnancy? Was labor prolonged and difficult? Was it a breech delivery? Breech births are more susceptible to cerebral hemorrhage. Was it a long and exhausting labor and were forceps applied as a last expedient? Was morphine or nembutal administered? If so, how much and how long before the delivery of the baby?

A narcotized infant can be recognized by its inactivity, drowsiness, cyanosis, the difficulty with which it is made to cry, the slow heart action, and perhaps, though rarely, pin-point pupils.

Cerebral edema and cerebral hemorrhage are sometimes very difficult to distinguish. The final diagnosis may sometimes not be made until many months have elapsed and the infant has developed into a normal baby; then one often revises the diagnosis from hemorrhage to edema. Even then one cannot be certain, because many a case of multiple punctiform hemorrhages of the brain clears without leaving any residual symptoms. In the long run, as far as therapy is concerned, it makes little difference whether a diagnosis of edema or hemorrhage of the brain has been made, because the therapeutic measures to be undertaken are more or less similar in the two conditions. An infant whose cyanosis is intermittent rather than continuous is usually suspected of suffering an intracranial injury. Intracranial hemorrhage is of the meningeal type in the large majority of the cases. If the hemorrhage is cortical, convulsions are more apt to occur than when it is basal. In infratentorial hemorrhage, the symptoms are more severe, cyanosis more profound, and breathing more labored, because of the greater pressure exerted upon the respiratory center. There may or may not be difficulty in initiating respiration. The infant may respond well soon after birth and not exhibit any signals of trouble for twenty-four to forty-eight hours or even seventy-two hours. Occasionally, though more rarely, symptoms may not set in for three to four weeks after birth. If the intracranial pressure is increased, the pulse may be slow, respirations irregular, intermittent or continuous cyanosis, the anterior fontanel is bulging, there may be rigidity of the extremities, increased reflexes, nystagmus and sometimes retinal hemorrhages are demonstrable. Any infant that cries continuously soon after birth, or is unusually somnolent, refuses to nurse, is unable to swallow or vomits—and particularly if it is of the explosive type—should be suspected of suffering from cerebral edema or hemorrhage. A very helpful diagnostic pointer of cerebral trauma which the author

has observed is the following picture: an infant who has grunting respirations similar to the expiratory grunt of pneumonia in older children, or has sighing respirations, and whose cheeks and lips pout and collapse rhythmically with each expiration, accompanied by foaming saliva at the front of the mouth or between the lips, most frequently has some intracranial birth trauma. The spinal or cisternal puncture is by no means a certain diagnostic procedure. Clear fluid has been obtained in cases that later proved to be undoubted cerebral hemorrhages; on the other hand, about 10 per cent of all newborn infants may show red blood cells in the spinal fluid, although they show no signs of cerebral hemorrhage and later develop no residual symptoms. Furthermore, the finding of a xanthochromic fluid is no sign of hemorrhage, because icterus may give the same discoloration, although it must be admitted that a positive benzidine reaction for blood on a xanthochromic fluid should make one suspicious of hemorrhage. Also the finding of crenated red blood cells in the spinal fluid may point to hemorrhage rather than to blood resulting from trauma of the plexus of veins in the spinal canal. In a word, when a spinal puncture is undertaken, one must evaluate the findings very carefully and with an unbiased mind and correlate them with the clinical findings and history of the individual case.

Phrenic nerve injury is diagnosed by the presence of an associated brachial palsy, lagging in the expansion of the lower half of the chest on the affected side and a demonstration by the fluoroscope that the diaphragm is not contracting on the affected side. Diaphragmatic hernia is usually found on the left side. Bizarre and changing physical findings in the chest make one suspicious of the condition. The finding of dulness in the thorax, to be replaced by tympany at the next examination, is a warning of its presence. The heart may be displaced to one side, usually to the right. The upper abdomen may appear collapsed, because the viscera are in the thoracic cavity. A simple x-ray film of the chest may confirm the diagnosis, although sometimes it becomes necessary to administer barium to the infant before the roentgenologic examination is made.

Pulmonary atelectasis is difficult to diagnose clinically unless it is very extensive, in which case areas of impaired resonance are found with absent breath sounds. The cyanosis in those cases is usually of the continuous type. If a whole lobe or the greater part of it is collapsed, one usually finds the heart drawn over to the affected side. The *x*-ray examination of the lungs makes the final diagnosis certain. If pneumonia has developed, there are in addition to the continuous cyanosis, a septic temperature, rapid respiratory rate, cough, and auscultatory signs of pneumonic consolidation. Pneumonia of the newborn is much more common than is generally believed, and it is usually an aspiration pneumonia. Farber and Sweet⁹ demonstrated amniotic sac contents in the lungs of 88 per cent of 124 infants who died shortly after birth and they pointed out the importance of such aspiration as a cause of respiratory embarrassment in the newborn.

Enlargement of the thymus gland as a cause of cyanosis in the newborn, is much more rare than the frequency with which such diagnosis is made. Besides the cyanosis, there may be dyspnea, crowing sounds, such as result from laryngeal compression, and choking, particularly during feeding. Clinical demonstration by percussion of the enlarged thymus gland is only certain if the gland is very much hypertrophied. An *x*-ray study must be made of the infant's chest and neck in both views, anteroposterior as well as lateral. Only then should one be satisfied with the diagnosis of hypertrophied thymus gland, if all other common causes for cyanosis have been excluded, and if in addition to the clinical signs there is unmistakable roentgenologic evidence of hypertrophy associated with encroachment upon the trachea.

The diagnosis of a congenital heart defect as a cause of the cyanosis is easy, if one finds cardiac enlargement, a thrill and a definite murmur or murmurs. Sometimes only one or two of the above signs suffice for the diagnosis. One must bear in mind, however, that congenital heart disease may exist without any clinical signs. In some cases a murmur is not heard at birth, but becomes evident several days or weeks

later. In other cases, a murmur discovered soon after delivery later disappears altogether or changes in time and quality. Sometimes the x-ray examination of the heart may aid in the diagnosis of congenital heart disease, but more often—on account of the normally found globular-shaped heart in many infants at birth—the cardiac shadow as delineated by the x-ray only adds confusion to the problem. In any event, one is not very much amiss in failing to diagnose a congenital cardiac defect, because therapeutically there is practically nothing that one can do to relieve the condition.

Tetany is a disease entity that has been recognized of late as occurring in the newborn. Formerly it was believed that tetany is a disturbance that only affected infants after the third month of life. In the past few years, however, there has been an increasing number of cases of tetany in the newborn reported in the literature. Besides cyanosis, the symptoms that may be observed are laryngospasm, convulsions, carpopedal spasm or, in its absence, a positive Trousseau sign and a positive Chvostek (facialis) phenomenon. Increased excitability to the faradic current (Erb sign) and a decreased blood calcium with a high blood phosphorus content make the diagnosis certain.

Treatment of the Various Causes of Cyanosis.—Whatever methods or measures are employed in the relief of the particular cause of the cyanosis, three general principles are to be observed and practiced in all cases, namely: (1) be gentle; (2) maintain the body heat; (3) clear the air passages before any attempt at respiration is made. We need not emphasize here how labile the newborn, and particularly the premature infant is; how easily bones may be broken or dislocated if too vigorous attempts are made to initiate respiration; how frequently small hemorrhages in the brain may become more extensive if the, forever to be forgotten, Schultze swinging method of resuscitation is practiced. Whether artificial respiration by rhythmic contraction of the thorax is practiced, or whether the lower half of the body is rhythmically compressed against the chest, or whether mouth-to-mouth insuffla-

tion is practiced, one must be gentle and unhurried in carrying out the procedures, or harm will result. In the last-mentioned method, gentleness is paramount, otherwise rupture of the alveoli may follow. The sudden change from the warm intra-uterine surroundings to the cool room temperature, while it is considered by some as beneficial in that it helps to stimulate respiration, nevertheless, if continued too long will lead to excessive heat loss, shock, loss of weight and other unpleasant complications. Immediately after the baby is born, it should be wrapped in warm blankets and kept in a heated bassinet or incubator, where all the necessary toilet of the eyes, cord and skin should take place. Clearing the air passages of foreign débris before any attempt at respiration is made will obviate much trouble and cyanosis later. In fact, the best time to first aspirate is when the head has been delivered, but before the remainder of the body has been extracted; otherwise the sudden change from the warm intra-uterine cavity to the cold air may initiate the first gasp, and material will be inhaled causing not only cyanosis and asphyxia, but also pneumonia. Usually the compression of the chest that accompanies perineal deliveries expresses most but not all of the débris and mucus from the respiratory tract. However, in cesarean sections and also to some extent in breech deliveries, thoracic compression does not take place and hence more thorough aspiration of mucus must be instituted.

Aspiration is usually performed by means of a small cannula attached to a piece of rubber tubing. A glass bulb to catch the aspirated material is inserted between the cannula and rubber tubing. Suction is practiced by mouth. With this method most of the foreign material present in the mouth and pharynx can be removed. In many infants cyanosis recurs after they are brought into the nursery and in them the cyanosis may be due to thick mucus or blood in the rhino- or laryngopharynx. The author has found the following method very helpful in removing the foreign material from those parts: a number 8 or 10 French catheter is attached to an ordinary nose and throat suction apparatus, preferably one whose suc-

tion power can be regulated. The catheter can be introduced into the nose, laryngopharynx and occasionally even upper laryngeal aperture; gentle suction is applied. It is amazing how much mucus and débris can be removed thus, which the ordinary cannula could not reach. Furthermore, the cannula is likely to traumatize the mucosa of the mouth and pharynx, whereas the soft thin rubber catheter is quite harmless.

After the foreign material has all been cleared away from the respiratory pathway, the next most important step in the treatment of the cyanosis is the administration of either a mixture of 5 per cent carbon dioxide and 95 per cent oxygen or pure oxygen alone. There is some controversy as to which of the two is more indicated. Henderson¹⁰ says: "After birth the infant breathes in response to the same stimulus and by the same mechanism as those which the modern physiology of respiration has shown obtained in adults, in children, and in all mammalian animals. In all these, and in the infant no less, the maintenance and regulation of breathing depend on the carbon dioxide brought to the respiratory center in the blood. Oxygen is requisite if the center itself is to be maintained in normal condition, and if the tissues are to produce carbon dioxide, for deprivation of oxygen necessarily decreases the production of carbon dioxide. But the center may be quite normal and also quite inactive in the presence of ample oxygen if the blood is deficient in carbon dioxide. If the center has become inactive, or if its activity is subnormal, there is one, and only one, stimulus that will both restore and maintain normal activity; an increase of carbon dioxide in the blood. . . . It is as certain as anything in the whole range of modern science that respiration is under a chemical control by the more or less direct action of the arterial blood, chiefly through its content of carbon dioxide, on the respiratory center in the brain. It has been proved also that oxygen is not a stimulant, a fact which clinicians seem to find extremely hard to appreciate. . . . Asphyxia is usually thought of as a condition of oxygen deficiency and excess of carbon dioxide. This is a misconception; asphyxia usually, as in the typical condition of carbon monoxide

poisoning, involves both low oxygen and low carbon dioxide content in the blood and tissues. . . . It is the carbon dioxide carried by the blood from the tissues to the brain that is the physiologic stimulant to respiration. When the center is depressed it requires more than the normal amount of this stimulant to induce activity." On the other hand, Kane and Kreiselman¹¹ who studied the carbon dioxide content of the cord blood in 7 asphyxiated, 26 gasping and 14 crying infants, found that the carbon dioxide content in the newborn is consistently high and that the proportion of carbon dioxide increases with the degree of asphyxia. (In the 7 asphyxiated infants, the carbon dioxide averaged 54.6 volumes per cent.) They reasoned therefore that the addition of carbon dioxide to oxygen as a resuscitating agent is contraindicated; in fact, they found that the instillation of pure oxygen into the lungs was sufficient to initiate respiration in the newborn. Similarly, Eastman¹² who made some very valuable studies on fetal blood, concluded that the use of carbon dioxide as a resuscitating agent in asphyxia neonatorum is not only superfluous, but may even be harmful, in that it tends to aggravate an already existing acidosis. He, therefore, advocates the employment of oxygen alone as the therapeutic agent for the treatment of cyanosis or the graver condition, asphyxia neonatorum. Whether one employs oxygen alone or oxygen in combination with carbon dioxide, it is a most useful and certain adjunct in the therapeusis of cyanosis. It may be administered through a mask applied over the face of the infant or by means of a number 8 or 10 French rubber catheter inserted into the nostril of the infant, so that the tip can just be visible in the mouth at the level of the soft palate. The administration is at first continuous and, depending upon the severity of the individual case, intermittently for twelve to twenty-four to forty-eight hours or even longer if necessary.

Where other methods of aiding respiration had been tried without beneficial effect, the infant respirator has been used successfully. The principle of the Drinker respirator consists in placing the infant in a metal box, fairly airtight, with

the head protruding. One electric motor institutes negative pressure, thus inducing inspiration as a result of air entering the lungs through the nose and mouth. As atmospheric pressure is restored within the respirator, expiration occurs as a result of the elastic recoil of the chest. This, as well as a modified form of the Drinker respirator, has been used successfully, not only in full-term, but also in premature and immature cyanotic and asphyxiated infants. In the absence of a tank of carbon dioxide and oxygen or of oxygen alone, mouth-to-mouth insufflation is a very valuable adjunct, provided it is done gently. With a piece of sterile gauze placed over the infant's mouth, the operator gently blows his breath into the infant's mouth at the rate of about twenty to twenty-four times per minute. However, here as well as with the use of a mask over the baby's face, gentleness is the watchword, otherwise alveolar damage might result. When we remember that the exhaled air contains 16 per cent oxygen and 4.38 per cent carbon dioxide, we realize why it is a valuable substitute as a respiratory stimulant.

If the cyanosis is the result of intracranial hemorrhage, in addition to administering carbon dioxide and oxygen, the infant is kept warm, and disturbed as little as possible. If the fontanel is bulging and signs of increased intracranial pressure are evident, periodic spinal tapping is advocated until the pressure is normal, but the procedure should be carried out with a minimal amount of handling of the baby. If it is suspected—as a result of a family history of bleeder's disease or a prolonged coagulation time—that a spontaneous rather than a traumatic hemorrhage is the underlying condition, then and only then should parental blood, in amounts of 15 to 30 cc., be given intramuscularly and repeated in twenty-four hours if there is no improvement, or larger amounts of blood may be transfused intravenously. Sedative drugs—particularly phenobarbital in adequate dosage—are indicated where restlessness is a prominent symptom.

There is, of course, very little that one can undertake in the treatment of cyanosis that is caused by a congenital cardiac

defect, except perhaps to relieve the symptoms by the administration of oft-mentioned physiologic stimulant. Where an enlarged thymus has been definitely diagnosed as the cause of cyanosis, an immediate x-ray treatment will usually give prompt relief; occasionally, however, the thymic symptoms are temporarily aggravated immediately following the exposure to the x-ray. In infectious states, particularly pneumonia, besides carbon dioxide and oxygen, frequent changing of the infant's position, blood transfusion and appropriate treatment of the underlying infection is the method of procedure. In the treatment of atelectasis, besides the periodic insufflation of carbon dioxide and oxygen, repeated stimulation of the infant to crying is indicated. The treatment of cyanosis due to tetany consists in administering parathormone and calcium—preferably the gluconate—intramuscularly, later continuing the calcium orally for some time and either keeping the infant on breast milk or placing it on an acidified milk formula. In hypoplasia of the mandible, Eley and Farber,¹³ who reported 5 cases, recommended postural treatment, *i. e.*, placing the infant on the face and elevating the remainder of the body. This usually relieves the mild cases; if the micrognathia is severe, a simple brace to hold the mandible forward and at the same time exerting pressure against the floor of the mouth and base of tongue has been used with success. Cyanosis or asphyxia resulting from overnarcotization is best treated by the application of external heat, oxygen, alpha-lobeline $\frac{1}{40}$ to $\frac{1}{20}$ grain intramuscularly or intravenously, artificial respiratory efforts and finally the Drinker respirator. In employing alpha-lobeline, one must remember that its action as a respiratory stimulant is very fleeting and may therefore be repeated at fifteen- to thirty-minute intervals if necessary.

Vigorous spanking, slapping the infant, dipping it alternately in warm and cold water, thus chilling and shocking the infant, blowing cigarette smoke into the baby's mouth, rhythmic traction of the tongue, dilation of the sphincter ani, pouring ether on the baby, and many other similar measures that are in vogue in one clinic or another, are all crude and primi-

tive; some are unphysiologic, and most of them are productive of more harm than good.

CLINIC OF DR. THOMAS J. COSTELLO

DEPARTMENT OF GYNECOLOGY, JEFFERSON MEDICAL COLLEGE

TREATMENT OF CHRONIC ENDOCERVICITIS AND VULVOVAGINITIS

TREATMENT OF CHRONIC ENDOCERVITIS

CHRONIC endocervicitis is probably the most common and, at times, the most difficult gynecological condition to treat. This is readily explained when the histologic anatomy of the cervix is studied.

The cervical canal is $1\frac{1}{4}$ inches in length, measured from the external to the internal os. The wall of the canal presents an anterior and posterior longitudinal ridge, from each of which proceed a number of small oblique columns, the palmate folds, giving the appearance of branches from the stem of a tree. To this arrangement the name "arbor vitae" is applied.

In the upper two thirds, the canal is lined with columnar, ciliated epithelium and is provided with racemose glands which secrete a clear, viscid, alkaline mucus. In the lower one third the mucous membrane presents numerous papillae and there is a gradual transition in the epithelium to stratified squamous close to the external orifice. On the vaginal surface of the cervix the epithelium is stratified squamous. It is not uncommon for the columnar epithelium to be continued a little outside the external os, appearing as a well-defined bright red area, circular or possibly irregular in outline. The racemose glands have narrow, tortuous ducts and provide an ideal location for bacterial growth. The inaccessibility of these glands within the folds of mucosa makes it quite difficult to reach them with ordinary chemicals.

Infections and traumatic lesions of the cervix will very

often cause an alteration in the usual relationship between the columnar and squamous epithelium. This again is manifested by a bright red color when the cervix is exposed with a speculum.

The following conditions may give rise to this typical appearance: (1) "pseudo-erosion"—a congenital extension of the mucosa of the cervical canal beyond the external os; (2) "ectropion"—an acquired extension of the mucosa of the cervical canal beyond the external os, caused by infection of the mucosa; (3) "eversion of the cervical lips"—causing exposure of the cervical mucosa. This may be a congenital split or resulting from a laceration during labor or abortion; and (4) "true erosion" of the cervical mucosa with primary loss of surface epithelium brought about by infection or trauma (mechanical, chemical, or thermal). Any combination of the above-mentioned conditions may exist and the appearance may be further distorted by the development of nabothian cysts which result from the blocking of the ducts of the cervical glands.

The object of treatment is to destroy infection within the cervical canal or upon the vaginal surface of the cervix, to correct everted lips, to obliterate distended glands, or to remove hypertrophied cervical lips. Cervical and urethral smears should precede any form of treatment.

To destroy infection, treatment should endeavor to localize active infection and promote drainage. When the cervix is hypertrophied and contains cysts, hot douches and puncture of the follicle with a cautery will help. If drainage is poor the os should be gently dilated, especially in the nulliparae. Topical applications of various antiseptics may be tried after first removing the mucous plug with a solution of sodium hydroxide (10 per cent). For this purpose silver nitrate solution (20 to 50 per cent), mercurochrome (20 per cent), or tincture of iodine are serviceable. Tampons covered with petrolatum should be inserted in the vagina following these applications and removed in six to eight hours. The patient is then instructed to take a daily douche and the topical ap-

plication repeated in one or two weeks. When the cervical condition is improved operative or cautery treatment may be instituted.

In the gynecologic department at Jefferson Hospital the cautery is the method of choice in treating chronic endocervicitis. It is well to remember the necessity for preserving the cervix for future pregnancies if the patient is in the child-bearing period. It is also important to have the cervix clean and to be certain that there is no active infection present. When eversion alone exists, cauterization of the everted lips will suffice to correct the condition. In the nulliparae when the os is constricted it is desirable to split the cervical lips, expose the entire mucosa of the canal, and then cauterize the involved area. Following this procedure a stitch is placed at the summit of the cervical incision. This prevents an adherence of the cervical lips. In virgins and women of child-bearing age, cauterization should be limited to a depth of 5 mm. In multiparae the cervical os is usually open and the canal accessible.

The contraindications to cauterization are acute cervical infections and the existence of an acute or subacute salpingitis. Pregnancy is not necessarily a contraindication to the use of the cautery. Breckenbridge and Whitehouse have shown that this method is safe and advisable in treating chronic gonorrheal endocervicitis in pregnancy. However, it is well to remember that the injudicious use of the cautery during pregnancy may cause abortion.

The complications that may result from cauterization are: (1) vaginal burns, (2) hemorrhage, and (3) stenosis. Burns are best prevented by thoroughly drying the vagina and cervix when an alcoholic solution is used for cleansing, and by protecting the mucosa of the vagina with retractors and moist gauze. Hemorrhage may occur immediately or seven to ten days afterward as the result of sloughing. This is best treated by keeping the patient quiet in bed or by gently packing the vagina. Stenosis can be prevented by dilatation when necessary.

After cauterization the patient is advised to avoid tub baths and not to douche unless the discharge is very annoying. If such is the case a solution of potassium permanganate (1:5000) used as a douche is permissible after the tenth day.

Persistent cervical infection is most frequently gonorrheal in origin. It is important that any foci in Skene's tubules, Bartholin's glands, and the urethra be destroyed and the patient cautioned against reinfection.

Other plans of treatment are advocated which in some instances are helpful. The use of the Elliott apparatus for producing pelvic heat is beneficial particularly when there is adnexal involvement. Desjardins, Stubler and Popp have reported good results in using fever therapy in treating gonorrhea. Hyams and Crossan report success with the radio knife. Their technic is to core out the mucous lining of the canal without destroying the musculature. Ende and Cherry recommend coagulation of the infected mucosa to a depth of 3 to 5 mm. Tovey employs copper ionization.

Operative procedures to correct hypertrophy of the cervical lips may be necessary especially after the menopause, and should be undertaken only by those well trained in the treatment of gynecologic conditions. For complete surgical details the reader is referred to textbooks dealing with the operations of trachelorrhaphy and trachelectomy.

TREATMENTS OF VULVOVAGINITIS

Vulvovaginitis may occur at any period in life. In childhood the vaginal mucosa is quite susceptible to infection and this is also the case in those past the menopause. Between puberty and the menopause the vaginal epithelium is more resistant to infection but during this period it is subject to such devitalizing influences as trauma, irritating discharges from the cervix, and constitutional disturbances, factors which predispose to infection. The exciting cause is some microorganism, animal parasite or fungus. The treatment, therefore, will depend upon the age of the patient and the causative factor.

Before any form of therapy is considered smears should be made and a definite diagnosis established.

GONORRHEAL VULVOVAGINITIS IN CHILDREN

The treatment of gonorrheal vulvovaginitis in children is always difficult. Cleanliness is the prime essential and frequent bathing with soap and water will help to remove any discharge from the external genitalia. The child should have its own clothing, towels, etc., and must be kept from contact with other children. Douches are necessary and can be administered by the mother after proper instruction. Antiseptics that irritate the mucosa are contraindicated. Potassium permanganate (1:5000) or boric acid solution, in gallon quantities, are not irritating. The interior of the vagina may be treated through a Kelly cystoscope with the child in the knee-chest or Trendelenburg position. For this purpose silver nitrate or mercurochrome may be used.

Gonococcus vaccines may be tried but the results are questionable.

The use of estrogenic substance has given good results in some cases. Lewis suggests using 100 rat units of theelin daily, diminishing the dose as a reaction is obtained by maintaining a vigorous squamous cell proliferation. TeLinde and Brawner report success by using amniotin in oil. They state that amniotin in suppository form has proved effective in producing mature vaginal epithelium and good therapeutic effects in gonococcal vaginitis in all cases in which they tried it.

GONORRHEAL VULVOVAGINITIS IN ADULTS

The treatment is general and local. Rest is essential, the diet should be light, mild laxatives are indicated to keep the bowels open, and the urine should be rendered alkaline. The vulva should be cleansed frequently with "pitcher douches" of potassium permanganate (1:5000) or bichloride of mercury (1:4000). After these irrigations bathing the parts with castile soap and warm water and then drying with cotton is a good procedure. Hot applications of lead water and laudanum,

witch hazel, or boric acid solution will relieve vulvular itching and burning. When the acute symptoms subside the vulva and vagina may be painted with silver nitrate (5 to 10 per cent) or mercurochrome (5 per cent). Douches of Lugol's solution or "A. B. C." powder (alum $\frac{1}{2}$ ounce, boric acid 3 ounces, phenol $\frac{1}{2}$ ounce, oil of peppermint 5 minims) using a teaspoonful to 2 quarts of warm water, are cleansing and will promote healing. Curtis recommends the blowing of powders into the vagina. Foci of infection in Skene's tubules, Bartholin's glands, and the cervix should be removed.

SENILE VULVOVAGINITIS

Treatment should be directed toward improving the general health and removing the cause. Silver nitrate (2 to 10 per cent) applied locally to the vagina will often give good results. This is followed by the insertion of a tampon covered with cold cream. Douching with 0.5 per cent lactic acid solution will aid in restoring vaginal flora. Estrogenic substance (amniotin or theelin) is sometimes beneficial. The urine should be examined carefully and any abnormalities corrected. Strong soaps or irritating douches should be avoided.

YEAST VULVOVAGINITIS

Gentian violet in a 1 per cent aqueous solution is practically specific for this type of infection. After properly exposing the vagina, and drying the mucous membrane, a cotton applicator is dipped in the gentian violet solution and used to paint the entire vaginal mucosa. A dry tampon may then be inserted in the vagina to lessen the amount of solution that may escape. The patient is then instructed to use a mercuric chloride douche (1:4000) each morning. The application of gentian violet should be done two or three times weekly until the monilia have disappeared from the vaginal secretion.

Gentian violet is sometimes very irritating to the inflamed mucosa of young girls and elderly women. In these cases 5 per cent mercurochrome solution or 1:5000 metaphen solution may be tried.

TRICHOMONAS VAGINALIS VULVOVAGINITIS

There are many forms of treatment, none being specific, which will result in a cure if used frequently over a period of time. The first requisite is thorough cleansing of the vaginal mucosa with tincture of green soap, and secondly applying an antiseptic to destroy the parasite. For this purpose 5 per cent mercurochrome, 1 per cent methylene blue solution, or 5 to 10 per cent silver nitrate solution are serviceable. This should be done frequently and the patient advised to use daily douches of lactic acid solution (1 teaspoonful to 1 quart of water). The use of 1 per cent picric acid suppositories as recommended by Goodall are helpful. Foci of infection should be searched for and eliminated. Probably the most important item in treating this condition is persistence.

OTHER FORMS OF VULVOVAGINITIS

Actinomycotic vulvovaginitis is treated by surgical excision of the granules and the administration of iodides in large doses internally.

Anginal Vulvovaginitis.—Application of potassium permanganate in the proper strength for swabbing or douching and a paste of neoarsphenamine are used to good advantage.

Diphtheritic Vulvovaginitis.—Here appropriate doses of diphtheria antitoxin must be given supplemented by local irrigations with a mild antiseptic solution.

Nonspecific Vulvovaginitis.—In the treatment of this form cleanliness is of prime importance. Douches and instillations of antiseptic solutions are indicated and any general local cause must be removed.

CLINIC OF DR. O. H. PERRY PEPPER

UNIVERSITY OF PENNSYLVANIA

NOTES IN THE FIELD OF GERIATRICS

DISEASE in old age differs in many ways from disease in other periods of life; the incidence of the various disease processes is not the same as in childhood or in middle age; the symptoms of a disease in the aged may vary considerably from the so-called "classical picture" of that disease. Similarly, the prognosis is not the same, and our treatment of disease in the old must usually be modified from our usual procedure and the inevitably limited goal of treatment in the aged must always be kept in mind.

These differences, inherent to the aging organism, are the basis upon which the science of geriatrics rests in exactly the same manner as pediatrics is concerned with the peculiarities and potentialities of the growing child.

Geriatrics is concerned with the prolongation of life, with the maintenance of physical and mental health, the relief of suffering, the lessening of the handicaps of age and the diagnosis and treatment of such diseases as occur. These are worthy aims and one need not apologize for an interest in geriatrics. Obviously it lacks some of the appeal of pediatrics for it deals with the body in involution, not in evolution. Yet it is an important subject with an increasing field of usefulness as more and more of the population are surviving past middle age. One might facetiously claim that of the two it is geriatrics which is the growing science while the falling birth rate suggests that pediatrics is a dying specialty.

CHANGES OF SENESCENCE

It is often said that old age is itself a disease but this is not true and one must distinguish between normal physiologic old age which is called senescence and abnormal pathologic old age which is by some termed "senility." The drawing of a line between the two is not easy for the physiologic changes tend to resemble and merge into the pathologic processes common in the aged. The distinction is, however, of the utmost importance.

In order to draw this distinction we must first become familiar with the physiologic changes appropriate to the age of our patient, just as the pediatrician does. These form a sort of base line; we accept them as our patient's normal even though the findings be very much altered from those in the younger subject. In the diagnosis of disease in the old we must often ignore physiologic changes which might have great diagnostic significance if present in a middle-aged patient. And we must always remember that in the treatment of disease in the aged we must keep constantly in mind the so-called "normal state" of our patient and we must admit that our therapeutic goal is limited to the cure of the existing disease and to the restoration of our patient to a state proper to his years. To this point we will have to return later.

There is little need to mention graying of the hair except to say that it often occurs in quite young persons, especially in certain families with coarse black hair. As long ago as 1638, Francis Bacon wrote "Hasty gray hairs, without baldness, is a token of long time: contrarily if they be accompanied with baldness."

Similarly the well-known arcus senilis may occur even before middle age. Often this lipoid deposit may encircle the whole iris but it can never be employed as an evidence of great age nor of disease. It is an interesting fact that Nascher, the author of one of the most famous works on geriatrics, had an arcus senilis even as a young man; one cannot help wondering whether it was this precocious arcus which directed his life interest to the changes and diseases of old age.

The skeleton, on the other hand, shows increasing changes which are characteristic of advancing years. One of the most important is an atrophic thinning of the intervertebral disks which accounts for much of the bowing of the spine, also flattening of the vertebrae and a tendency to exostoses (Hrdlicka). The vertebral column becomes curved and shorter resulting in a loss of an inch or two in height. This forward bowing of the spine changes the shape and size of the thoracic cage and contributes in this way to the development of so-called "senile" or postural emphysema. The long bones and the larger flat bones become weakened from osteoporosis and approach the picture of Paget's disease. Many of the cartilages atrophy and become calcified.

All lymphoid tissue throughout the body atrophies as age advances. The tonsils exhibit this change even before the age of forty; the lymph nodes are markedly atrophied in the old. As a rule the thymus has almost disappeared—but it may sometimes be preserved. No effect of this lymph tissue atrophy can, however, be recognized in the number of lymphocytes in the circulating blood.

Almost all the organs atrophy and in the case of those whose function can be measured some reduction in functional ability is the rule. In those over seventy years of age the kidneys constantly exhibit atrophy and the usual tests of renal function reveal some impairment in almost 90 per cent of cases.¹ It is the phenolsulphonephthalein elimination test which most often gives abnormal results.

The thyroid is atrophied and the basal metabolic rate is usually lowered. The acid glands of the stomach are less evident and an anacidity is present in fully two thirds of the very old. The spleen, adrenals and liver become smaller especially the liver which may be reduced to half its normal adult weight. We have no satisfactory evidence that any of various functions of the liver are definitely impaired although it is true that in the aged the sugar tolerance test very often reveals a curve suggesting a marked storage defect.

The lungs constantly reveal emphysema and this state

must be accepted as physiologic in the aged. Whether it results from the postural changes due to spinal curvature, or from simple atrophy of elastic tissue, it is apparently very different from the obstructive emphysema of youth and middle age. With the progress of emphysema and the weakening of the muscles of respiration the vital capacity decreases. On the average there is a loss of about 600 cc. as one ages from sixty to ninety years; males losing more in proportion to their higher initial level.²

The heart is an exception to the general tendency to atrophy—its weight may maintain its relation to body weight unchanged. In the old the pulse rate tends to settle to about 60 per minute; the blood pressure often rises until the age of seventy but then lowers or remains stationary.

It is true that changes do occur in the aorta and larger arteries with great frequency but these changes are of a special kind and must not be confused with true arteriosclerosis which is always pathologic. The arterial changes of senescence affect the media of the vessel wall—first as a degeneration and finally as a calcification. The result bears the name of Mönckeberg's sclerosis and although it greatly alters the artery to palpation giving it the so-called "bird's trachea" feel, the process causes little or no impairment of circulation; nor do the lengthening of the aorta or the calcified plaques so commonly revealed in the aortic arch by x-ray of the aged subject. Some capillary beds are greatly lessened in the old—especially perhaps in the skin giving rise to the deceptive "patriarchal pallor" which so often leads us into a mistaken diagnosis of anemia. By and large, the circulation of the very old is amazingly good; their electrocardiographs exhibit no constant abnormality and their tendency to heart disease is not great.

I hope by this time I have made it clear that one must know the normal of the aged in order to recognize the pathologic when it occurs and to diagnose disease. Let me drive home my point by reference to one more organ or system.

The brain in the old becomes smaller and increasingly firm; the meninges are often adherent and areas of calcification are

common. The functional changes are only too well known—merging from mere forgetfulness as one reaches one's anecdotal age into the definitely pathologic states of senile dementia. More important for neurologic diagnosis perhaps are some of the changes which normally take place in the reflexes and sensation of the aging person and which may readily lead us into error.

For example, the tendon jerks lessen and even disappear—the achilles reflex being the first to be lost; only late is the knee jerk ever absent. The abdominal reflex tends to be lost rather early in senescence—but the plantar reflex persists. Loss of vibratory sensation especially in the lower extremities commences even as early as fifty and is often markedly impaired by the middle sixties. Sense of position is also impaired and there may be some diminution in perception of touch and pain. These findings could easily be used to bolster up a faulty diagnosis. The pupil of the old is small unless cataract is present and recognition of contraction to light may be difficult. The senile tremor of the aged has a rate of about 100 per minute and is not by any means to be confused with true parkinsonism.

Finally, it is worthy of note that some loss of weight seems normal for the aged. At least 5 to 10 pounds is apt to be lost after the age of sixty without there being any recognizable pathologic cause. One cannot help wondering whether this change and perhaps some of the others already enumerated may not be beneficial to the aging organism. It would be easy to argue that the loss of weight, the lower metabolism, the slower and less violent muscular movements, the diminution of sex function all tend to lessen the demands made upon the heart and circulation. It is enough for our thesis today, however, if we accept these changes as physiologic and distinguish them from the truly pathologic processes which occur.

DISEASES OF OLD AGE

An attempt has often been made to divide the diseases seen in old age into two groups, one containing those ailments which

occur as a rule only in the aged; the other those found in younger age groups as well. Such a division is of necessity somewhat arbitrary and inaccurate.

The famous French neurologist Charcot named as the characteristic diseases of age—senile marasmus, senile osteomalacia, atrophy of the brain, and circulatory weakness from heart weakness and arteriosclerosis. You will see that these changes include several which we have classed as physiologic.

Lewellys F. Barker includes Paget's deforming osteitis, osteoporosis, malum coxae senilis, senile anorrhæxia, diverticula of the esophagus and intestine, coproliths, bronchial catarrh, emphysema, prostatic hypertrophy, cerebral atherosclerosis, senile dementia, paralysis agitans (nonencephalitic) and hyperkeratoses. Again we find listed as diseases some changes which I have preferred to put among the physiologic changes of senescence.

Diseases of the Digestive Tract.—We have already noted that the aged are apt to lose weight, to have little appetite and to lack gastric secretion of acid—all of these without organic disease. This must not, however, lead us to overlook the frequent instances in which the aged do develop lesions of the digestive tract.

In the esophagus of the old, pressure diverticula are quite common; these are the pressure type and result from an actual herniation of the mucous membrane through the weakened muscular coats. They are apt to occur at one of two points, either where the esophagus is narrowed as it is crossed by the left bronchus or higher where the esophagus and pharynx join. Difficulty in swallowing may be a symptom and one must not confuse this with the more or less physiologic slowing of the act of deglutition which can be demonstrated by x-ray in the aged. Cases of diverticula are not rare from the age of seventy on.

The stomach is a frequent seat of carcinoma in the aged and like many diseases at this time of life the process may be amazingly latent. There may be few symptoms and these few

are apt to be explained away as due to the patient's age. Vomiting may not occur and pain is often wholly absent.

Ulcer of the stomach, on the other hand, is increasingly rare as age increases but a case reported by Cheney and Garland³ exhibited a definite ulcer of the posterior wall of the stomach in a patient ninety-six years of age; there was no sign of malignancy.

Acute appendicitis used to be thought to be rare in the old but a number of excellent reports^{4, 5} force us to admit its fairly common occurrence in the seventies and even occasionally in the eighties. The picture differs in certain important features from acute appendicitis of earlier age periods. The onset is usually less acute; there is less pain, less fever, less vomiting. Fever may be absent, the pulse not over 100, the leukocyte count not over 15,000. As a rule the diagnosis is delayed under the belief that one is dealing with some form of partial intestinal obstruction. This diagnostic error seems to be difficult to avoid. When peritonitis develops the pus is apt to be scanty and greasy. Correct diagnosis is important; for the treatment even in the very old is surgery which is remarkably successful.

True intestinal obstruction also occurs frequently in the aged, from various causes. It is predisposed to by the lessening power of the intestinal musculature. Occasionally the obstruction is found to be due to a gallstone which has silently ulcerated its way from the gallbladder into the bowel. Dr. Ravdin operated upon such a case for us at the University Hospital a few years ago. The stone could be felt through the seventy-four-year-old woman's emaciated abdominal wall. Coproliths also may lead to obstruction, and in lesser degree fecal accumulation in the lower bowel may increase the habitual constipation of the elderly and occasionally give rise to periods of irritative diarrhea. In passing it is worthy of note that the first mention of the use of mineral oil for constipation was by John Floyer in 1724 in a work entitled "The Gallenic Art of Preserving Old Men's Healths."

Diverticulitis of the descending colon occurs in the old—

predisposed to by the long-standing constipation. The picture which results may be imagined from the name given to the condition—"the left-sided appendicitis of the elderly." A serious mistake can easily be made for the mass of thickened bowel, diverticula and plastic peritonitis may resemble even at operation a malignant process and perhaps be thought to be inoperable.

In the biliary system of the aged one finds hepatic cirrhosis not infrequently in the seventh decade of life and at all advanced ages gallstones are common. Fortunately, for the patient, colic is rare and the stone may pass down the duct or ulcerate into the bowel with little or no pain. Turner⁶ operated upon a man of eighty-one for obstruction of the bowel. The obstruction was found in the transverse colon and was due to what is claimed to be the largest gallstone on record—weight 5 ounces, length 3 inches, width $2\frac{1}{4}$ inches. The patient recovered. After this story we must go on to another system.

Diseases of the Genito-urinary System.—In this field there are two topics of main interest—kidney failure and prostatic hypertrophy and these two are often associated. With regard to kidney disease in old age we have already noted that tests of kidney function, especially the 'phthalein elimination test frequently shows some impairment without any indication of serious or progressive renal pathology. We may now add that true nephritis is not a common disease after seventy. Those individuals who have suffered progressive glomerular nephritis in middle age have usually dropped out of the race before this age is reached. Acute glomerular nephritis is rare and both acute and chronic nephrosis very infrequent.

On the other hand, some degree of nephrosclerosis or arteriosclerosis of the kidney is a very common finding at autopsy in the elderly. It is seldom the cause of death and the full picture of kidney failure from this cause is not common. Probably the situation is analogous to that regarding other arteries of the body; unless the arteries are good the individual does not survive into old age. For statistical purposes it is difficult

to draw the line between the arterial changes almost physiologic for old age and those of minor pathologic degree.

Kidney impairment from back pressure due to obstruction by an hypertrophied prostate is far more frequent than true nephritis or serious nephrosclerosis.

From whatever cause it arises a slight degree of nitrogen retention is frequent in the elderly but high azotemia and the classic picture of uremia are uncommon. Also true renal edema rarely if ever occurs in the aged. Usually there is a big cardiac element present and the cardiac failure overshadows the renal failure. Often the picture is confused—but seldom is the clinical picture or the underlying process that of a true chronic nephritis.⁷

Prostatic hypertrophy is so common as we pass the sixties into the seventies that one could readily include it in the list of changes physiologic to senescence. But certainly one progresses by imperceptible gradations from a symptomless enlargement into the full-blown picture of obstructive "prostatism" with renal damage, raised blood pressure and nitrogen retention. We need only remind ourselves of the rarity of true nephritis in the elderly male and the frequency of what may be called an obstructive nephropathy to make the resolution never to make the former diagnosis until we have excluded the latter. Digital examination by rectum is not sufficient for a median bar may cause great obstruction even without much general enlargement of the prostatic gland. Nor should we neglect the possibility of prostatic obstruction even in the very old—for it may first cause trouble in the eighties and may be operated upon successfully even in the nineties.

Diseases of the Lungs.—We have mentioned the emphysema and loss of vital capacity which always occur in age and sometimes the emphysema becomes of such grade as to deserve to be termed pathological. The other diseases of the lungs which deserve to be mentioned are chronic bronchitis, tuberculosis and pneumonia.

Chronic bronchitis often termed "senile catarrh" is an extremely frequent malady of the old—so much so that few es-

cape the annoyance of the resulting cough, expectoration and dyspnea. At times the fibrosis and dilatations of the bronchioles lead to bronchiectasis and in many instances some degree of congestion from weakening circulation further interferes with respiratory function. Cyanosis from these combined factors is a common symptom in the elderly.

Tuberculosis of the lungs at advanced ages is not as rare as one might anticipate. Many authors have emphasized this and the great Laënnec recorded the finding of pulmonary tuberculosis at the autopsy of an almost one-hundred-year-old individual. Some have even claimed that more old than young persons die from tuberculosis, but this is by no means an accepted fact. Much of the evidence is old and possibly open to question. Schlesinger⁸ in his extensive work on Diseases of Old Age emphasizes the importance of nutritional disorders, diabetes, influenza and trauma as favoring the breaking out of a latent or almost healed chronic lesion.

The x-rây evidence of pulmonary tuberculosis in the elderly is said to be simulated by the lung changes characteristic of old age so that this modern method of diagnosis may also lead us into error.⁹ On the other hand, syphilis seldom causes disease or death in the very old; some of its residua may be present in the aged, but its symptoms rarely appear first at that age.

Pneumonia usually of the lobular or bronchopneumonic form is very common in the old and is frequently fatal. True croupous lobar pneumonia does occur even at advanced age but bronchopneumonia is at least five times as common. The clinical picture in the aged may differ sharply from that in a robust individual of middle age. Indeed the symptoms may be so few that an octogenarian may seem to die of myocardial failure and the discovery of an extensive pneumonia at autopsy comes as a distinct shock. Cough, fever and expectoration may all be absent and there may be little or no leukocytosis and no pleuritic pain. Also the emphysema may help hide the consolidation on physical examination and one may attribute the râles to bronchitis and passive congestion.

Possibly some of the lack of symptoms of infection may

be explained if it is true that many instances of senile pneumonia commence with a local thrombosis rather than with a true pneumococcus infection.

Pneumonia has been called by Osler "the old man's friend" because it offers a short and often peaceful final step—but by no means are all cases of pneumonia fatal even in the very old. Parkes-Weber,¹⁰ the well-known British clinician, has recently reported recovery from acute pleuropneumonia at eighty-five and refers to recovery in a patient of one hundred and three who, however, developed a fatal gangrene of the foot during convalescence.

Certain of the characteristics of acute infections in the aged need to be mentioned.

Acute Infections.—It is generally said that except for pneumonia, influenza and erysipelas, acute infections are rare in the aged. This is statistically true—but other infections do occur and because unexpected are often overlooked or misdiagnosed. Even the so-called "childhood diseases" may occur late in life. Rolleston¹¹ has reported chickenpox at sixty-four and at seventy-six although Van Genser found no patient over sixty-five among almost 30,000 cases. Measles at seventy-one with recovery has been recorded.¹² And so on with other diseases.

There is one disease common to youth which shows no mercy to the aged. This is whooping cough. Many cases over seventy and not a few over eighty are on record—for example, the famous Sir William Jenner was attacked when over sixty-five years of age. Often the patient may give a history of an attack in childhood but this does not prevent the illness being severe and exhausting even to a fatal outcome. It has been emphasized¹³ that it is not safe for the old to have contact with cases of whooping cough for any earlier immunity may have been lost and the disease is more serious to the old than to younger adults. This is worth remembering for often the grandmother is called into service to care for a child.

Pneumonia we have discussed; influenza does not differ much from the picture in earlier life; but concerning erysipelas

it is worth pointing out that its frequency in the aged reflects the poor nutrition of their skin. In the old, itching is frequent and so is eczema; keratoses and excoriations are common. Like senile pneumonia erysipelas may cause little fever and leukocytosis, but may initiate acute pyogenic infection of the kidneys of serious import.

Incidentally, it may be noted that herpes zoster in the aged is apt to leave behind it persistent local pains. Also in the aged gangrene of the skin may follow very minor injury.

Finally with regard to all acute infections in advanced age, it may be said that circulatory collapse may occur early; respiratory complications are common; delirium is frequent, but fever, leukocytosis and splenic enlargement often fail to appear.

Diseases of the Skeleton.—In the skeletal system the lesions of the greatest geriatric interest are Paget's disease, fractures and multiple myeloma. In Paget's disease, we are faced again with the difficulty of drawing the line between the usual osteoporosis of senescence and the process which justifies the name Paget's disease and which may be responsible for severe pain, deformity and disability. Nor must we forget that Paget's disease may appear in persons younger than the age usual for senile osteoporosis. Although it is tempting to relate Paget's disease to hyperparathyroidism, the evidence seems still to be opposed to this view.

Fractures, especially of the thinned and weakened neck of the femur, were formerly one of the tragedies of old age. To-day while no less common the much improved results of treatment make the condition much less dreaded. Healing with union has been repeated in patients over ninety¹⁴ and even over one hundred.

Perhaps multiple myeloma is not common enough to be mentioned in such a hasty review as time permits today, but it is so apt to be overlooked and the pain, loss of weight and anemia blamed on something else that I cannot help reminding you that it is one of the diagnostic pitfalls in the elderly.

Diseases of the Endocrine Glands.—One is tempted to generalize that all endocrine functions tend to be lessened as

age advances and that distinct endocrine diseases are rare in the old. Both these statements are almost the truth. Nevertheless, it must be remembered that we are not yet sure that osteoporosis and Paget's disease of the bones are not related to disturbance of the parathyroids. Also thyrotoxicosis is commoner than one might at first think. A report¹⁵ of thyroidectomies for thyrotoxicosis includes 200 cases over the age of fifty and up to the age of seventy-six.

Loss of gonadal function is more physiological than pathological—but worry about the loss may almost become a disease. Witness the absurd lengths to which efforts at its restoration have gone. No measure has ever brought about true rejuvenation; at most a temporary erotization has been achieved.

The hypophysis continues to function even in the old, and the hypophyseal sex hormone has been found in the urine of old men,¹⁶ and Zondek¹⁷ has found prolactin in the urine of some women up to the age of ninety-six.

Diseases of the Cardiovascular System.—We have already noted that in the aged it is the rule for the myocardium to be a little weakened, for the larger vessels especially the aorta to be somewhat lengthened, tortuous and perhaps calcified and for the blood pressure to be a little high. Nevertheless, it is interesting how good the circulation is apt to be in the old. A recent study of 300 individuals between eighty and one hundred years of age reported¹⁸ from France supports these facts. Willius¹⁹ in this country found 45 per cent of 700 persons between seventy-five and ninety-six in age had no evidence of heart disease.

Heart failure is, however, a very important disease and is one of the most frequent causes of death in the old. Often the heart fails with little previous evidence of myocardial disease and with little of the usual picture of congestive heart disease. It is perhaps a failure of nutrition of the muscle—partly from lessened blood supply, partly perhaps from lowered blood sugar or similar factors.

True congestive heart failure is not rare and is often exaggerated by the pulmonary fibrosis and emphysema. The val-

vular lesion most characteristic of advanced age is pure aortic stenosis. It is more a matter of calcification than of arteriosclerosis and the aorta beyond may be remarkably healthy as Rolleston and Christian have emphasized. Osler is quoted as saying that such narrowing of the aortic orifice "helps make a man an octogenarian."

Extensive atheroma of the aorta may occur and may indeed lead to the nonluteic dissecting type of aneurysm known as the "aneurysm of old age."

Reports in the literature include one on the greater seriousness of sinus arrhythmia in the aged than in the young,²⁰ and one stressing the rarity of thrombo-angiitis in this age period.²¹

Personally, I have been impressed with the importance of transient lowering of blood pressure as the factor which precipitates arterial thrombosis whether cerebral, coronary, visceral or peripheral.²² I believe that many of the cerebral manifestations of the elderly result from thrombosis rather than from the hemorrhage or arterial spasm. The fact that a person's habitual blood pressure level is high does not constitute a valid objection to this theory for it is well known that the variations up and down of the blood pressure are even greater in the hypertensive than in the normal.

Diseases of the Nervous System.—One of the matters which needs special discussion here concerns the cerebral circulation for many of the psychoses of the aged result from poor cerebral blood supply. In fact, it is not unusual for mental confusion, delusions, transitory palsies, etc., to improve markedly and often unexpectedly when the heart action is improved.

Of course not all cerebral deterioration in the old is on a circulatory basis. True senile dementia would disprove any such view. Also there are cerebral changes which depend upon extreme pathologic arteriosclerosis and which will not respond to any treatment.

However, it should be emphasized that it is dangerous to assume too readily that mental changes are surely due to senility. This is especially true in the so-called "presenile

dementias" such as presbyophrenia, Alzheimer's disease and Pick's disease. To make such a diagnosis without careful exclusion of pernicious anemia, syphilis and frontal lobe tumor is inexcusable.

We have now touched on most of the diseases usually considered important in the field of geriatrics. We must, however, remember that our present-day success in the treatment of certain conditions formerly fatal in youth and middle age may lead to the appearance of these in greater numbers among persons of advanced years. For example, patients with pernicious anemia or severe diabetes mellitus did not often survive into advanced old age while today with liver extract and insulin it seems quite possible that they will. It is mere speculation but it is interesting to wonder whether the picture presented by such cases in old age may not be different from what we expect. How long will such replacement therapy continue to be effective? How will an aged individual withstand continued hypodermics of insulin? How will the various changes of senescence occur in an individual who is lacking in an ability to form his own antianemic factor? These are interesting questions which we cannot at this time answer. To date there seems no limit to the success of replacement treatment with thyroid substance. Means²³ has recorded a case of spontaneous myxedema who has for twenty years been kept in perfect control by a daily ration of thyroid substance until she has now reached the age of seventy-seven. We must be on the lookout for the thyroid needs of our numerous thyroidectomized patients as they get older.

Characteristics of Disease in the Aged.—Not only does geriatrics have its own list of diseases but these maladies have certain features in common. Most important is the absence of pain and of many of the expected symptoms. "The organs suffer in silence," writes Sir Humphrey Rolleston, "without any local or general disturbance though collapse may occur." The body fails to react and to make its struggle manifest. Fever is often lacking.

In the old, gallstones are common, colic rare, and the stone

may ulcerate through into the bowel without ever producing any pain; many other examples could be given.

Mental confusion is common even in the absence of obvious fever or toxemia. Lack of a will to live seems sometimes to determine a fatal outcome. An old person will sometimes simply fade into death during convalescence from some mild illness or after an apparently successful operation such as for cataract.

It is such deaths as these that seem almost physiologic—without definite pathological cause. It is of these that Warthin²⁴ wrote, deaths do occur from the “primary lesions of senility alone.” This is the most natural ending of life—and it is rare indeed! Warthin in his enormous experience only saw twenty-five such cases and in each of them he felt that death was in the last analysis due to myocardial inadequacy.

Treatment of Disease in the Aged.—And now finally let us discuss the treatment of disease in the aged. It is worthy of best attention—far more so than many a young physician is tempted to think. As Snowden²⁵ puts it: “Too often the tendency is to look upon the minor infirmities of old age as inevitable ones which the sufferer should bear in silence and the more acute illnesses as the beginning of the end.” Neither attitude is excusable—much can be done for the minor infirmities by a thoughtful physician and we all learn by experience what unexpected recoveries the aged may make from serious illness and how successfully they may undergo major surgery.

There is, it seems to me, a curious paradox in this matter of geriatric treatment which arises from the fact that the old react poorly to medicines but may stand surgery well. This means that we should be conservative in our medical treatment but not fear to take the risk of surgery when indicated. The danger is that we will employ too many drugs and from faulty timidity deprive our patient of a chance at surgical cure.

First, with regard to drugs. In general, it may be said that the aged absorb drugs slowly and that cumulative action is common. I have observed this especially with morphine and belladonna. Also it is true that sedatives may cause excitation

rather than the reverse and that they often bring about mental confusion or even delirium. Rolleston advises against morphine; Barker against chloral; even bromides may cause marked confusion. Whatever sedatives you employ—use a small dose and beware of delayed cumulative action. If your choice is morphine, it is well to combine with it a small dose of atropine to protect the respiratory center.

Belladonna is quite apt to excite the old and we are warned also to avoid the use of arsenic. Some even warn against digitalis although this is probably more a matter of dosage. In small daily ration it certainly seems to me to do much good; although I agree that in larger dose it may be definitely harmful.

It certainly seems reasonable that the aged organism can scarcely be expected to react to cardiac stimulants. The gist of the matter is contained in a favorite story of a very experienced physician at the Philadelphia General Hospital, to the effect that if your autopsy material is running low suggest to the interns that they are not being therapeutically active enough. For a few days the poor old wrecks of a city hospital's ward will show great signs of activity but then will come the final collapse.

Much the same reasoning applies to other diseases. I have seen an elderly diabetic made much worse by overenthusiastic dieting. Many old people have lived with their maladies for years and are more or less adjusted to this symbiotic state. The balance must not be too abruptly disturbed and remember always that the geriatric patient can only be restored to the state appropriate to his age—never to youth.

Often nursing is more important than doctoring. Often little matters determine the result. We must remember to adjust our efforts to the patient's long-established habits. For example, it is harmful to try with sedative to force an aged patient accustomed to five hours' sleep and the early awakening of the old to remain in sleep for eight hours until 8 in the morning. The old need rest and gentleness—but it is wiser

not to keep them in bed too long, for fear of hypostatic pneumonia and of insidious myocardial failure.

And, on the other hand, the aged stand surgery fairly well. Baily²⁶ put it as follows that the aged exhibit "unusual tolerance for serious major surgery," but as he quite properly states success depends upon preoperative study and postoperative care. He stresses the importance of short bed period and good cheer. Baily reports the results of major surgery in 185 patients whose ages range from sixty to eighty-four. The group included cases of appendicitis, intestinal obstruction, hernia, prostatic disease, cancer and biliary tract disease. The operative mortality for the series was 7.6 per cent.

Other reports of successful geriatric surgery include cataract operation²⁷ at ninety-six; gastric resection for carcinoma²⁸ up to seventy-eight; cholecystectomy²⁹ at eighty-six; operation on pharyngo-esophageal diverticula³⁰ in 3 cases all over seventy. But the prize report is that of Everidge.³¹ The patient aged ninety-five wished his hernia repaired at the time of his prostatectomy because his truss interfered with his golf. It is this spirit which if the flesh is healthy leads to longevity. An interest in life is a primary requisite.

CLINIC OF DR. P. S. PELOUZE

UNIVERSITY OF PENNSYLVANIA

THE TREATMENT OF THE COMPLICATIONS OF GONORRHEA IN THE MALE

OF first importance in gonorrhea is the prevention of complications, for with comparatively few exceptions, the complications of this disease do not need to be. Overwhelmingly they are precipitated by avoidable factors of patient conduct, hygiene or injudicious treatment. That this is so can be shown by a comparison of the number of complications in those individuals who have been subjected to these adverse influences with those occurring among gently treated, well-behaved patients. Such a comparison follows: an analysis of 750 cases, leaving out the question of posterior urethral involvement, which will be considered later, showed there were 207 complications at or before their first visit. While under gentle treatment with every effort made toward patient control, there were but 30 complications. A study of these 30 showed 19 cases of epididymitis, 16 of which followed gross misconduct on the part of the patient. In other words, there were but 11 complications in well-behaved patients. One of these was a case of arthritis immediately following the lancing of a para-urethral duct, and even this would not have happened if the procedure had not been done so early.

Thus we see that the number of complications depends mostly upon the three factors mentioned and, if we transfer the 16 cases of epididymitis occurring in noncooperative patients to the 207 present on admission, we find over nineteen and one-half times as many complications in the one group as

are found in the other. Regarding the presenting histories of those patients having the 207 complications there were few of them that reflected good conduct, good hygiene and gentle treatment.

Turning to the question of posterior urethral involvement, a close analysis of a smaller group of cases, 283, showed some very interesting figures. The purpose of this analysis was to get some idea as to the frequency of posterior infection under the plan of treatment used by the writer in regard to the time treatment was started. There were studied 100 consecutive patients presenting themselves for treatment before the sixth day of the disease and whatever number presented themselves at a later period of the disease but during the same length of time. This latter number was 183 cases. Of course many of these latter cases had received some type of treatment early in the disease.

Analyzing the 100 cases appearing before the sixth day it was found that 14 had a posterior urethral involvement on admission and 6 were noncooperative, leaving 80 who could be considered as good experimental animals. Of these 68 (85 per cent) failed to develop a posterior involvement while 12 (15 per cent) did.

Of the 183 patients presenting themselves on the sixth day or after, all but 12 had a posterior involvement when first seen and only 2 eventually escaped such disease extension.

In these latter figures it is outstanding that the percentage of posterior urethral infections with their concomitant prostatic involvement depends upon patient conduct and hygiene and the institution of gentle, careful local treatment prior to the sixth day of the disease.

Reverting to the prevention of the other complications, a study of the things done by patients and doctors immediately prior to their onset, gives us a large assortment of things that should not be done. The doctor faults center largely around the questions of lack of patient instruction, too early massage of the prostate gland, too forcible irrigations and the use of catheters, dilators and sounds. Patient faults are largely

matters of sexual excitement, alcoholic drinks, neglect and the trauma of self-treatment.

It is far from generally sensed that early, gentle treatment and increasing efforts to obtain and hold patient cooperation pay such enormous health dividends. Not only do they make the disease a milder and shorter one, but they take from the clinical picture at least 90 per cent of the unfortunate complications that do so much to make it a formidable health menace.

Today most physicians would express a belief that cure is dependent upon the patient's ability to engender the proper immunity responses. Despite this widespread belief there commonly are used many forms of treatment that one's wildest flights of imagination could not vision as immunity stimulants. And it is these forms of treatment that so commonly precipitate needless complications. Almost ceaselessly we dream of simpler forms of treatment, a state of mind that makes us avidly grasp at any new substance for which its originators claim simplicity and efficiency. We do not scrutinize the foundation upon which these claims rest, as we would in the treatment of almost any other disease, with the exception of the common cold, for which almost everyone will take almost anything. We largely have paid so little attention to what our efficient plans of treatment can do that one can bolster a report of value of his plan of treatment by the citation of some case histories that tell nothing and make it a story that carries conviction to the uncritical.

This, however, is not a discussion upon the treatment of gonorrhea but its complications, so let us take them up in the order of their frequency in the above mentioned series and briefly state more specifically how they can be prevented and how present thought says they should be treated if they do occur. There is no need that we talk more of posterior urethral infection, nor of its concomitant prostatic involvement unless the prostate is the seat of an acute swelling or a definite abscess formation. Otherwise both conditions are covered in any discussion on the treatment of gonorrhea itself.

EPIDIDYMITIS

Etiology.—The view that the gonococcus usually reaches the epididymis by means of infected urine forced down the vas deferens is the safest from the standpoint of prevention. (The mechanism and reasons for thinking so are discussed fully in the writer's book on Gonorrhea in the Male and Female, W. B. Saunders Co.)

Prevention.—The avoidance of high pressure irrigations or injections and digital manipulation of the subvesical structures until late in the infection is of the utmost importance. It should be insisted that the patient with infected bladder urine carry out no heavy physical exertions unless the bladder is practically empty, that he make no effort to hold urine for long periods of time and that, if he is going to be foolish enough to indulge in the sex excitations of petting, he at least should avoid vesical distention while the session lasts.

Treatment.—The most effective methods for the treatment of epididymitis are a dressing that gives both support and pressure to the inflamed structures (a tight jock strap or bandage), rest in bed if the temperature is above 101° F., and the intravenous injection of 10 cc. of a 10 per cent solution of calcium gluconate daily for four or five days. Patients with lower temperatures safely may be kept ambulant.

Either local heat or cold may be used and if definite abscess formation can be made out an epididymotomy should be resorted to. Such abscesses are extremely rare. Epididymotomy also should be considered in patients exhibiting prolonged high temperatures. This procedure usually gives quick relief from pain, but as prolonged high temperature cases and abscess formation are the rarity, it seldom will have to be resorted to. The local application of ointments to the scrotum seems to serve no good purpose.

ACUTELY SWOLLEN PROSTATE GLAND

Etiology.—The condition is usually the result of too early manipulations of the prostate gland. It sometimes occurs under the best of circumstances of conduct and treatment.

Prevention.—Let the prostate gland alone until the urethral infection has become decidedly inactive and then approach prostatic manipulations intent upon the utmost gentleness of procedure.

Treatment.—The best treatment for this condition is the application of heat to the gland in such a way that no trauma can result, otherwise epididymitis rather commonly is precipitated. Perhaps the safest way to apply this heat is by tying two catheters back to back so that one may serve as an inflow tube and the other as an outflow. Whatever type of apparatus is used should not be so constructed that it must be passed more than 1 inch beyond the anorectal junction. Unfortunately most of the rectal psychrophores must be passed much further into the rectum than this and are dangerous instruments to use under such circumstances. Water at 110° to 115° F. should be allowed to flow in and out for at least fifteen minutes twice in the twenty-four hours at first and then once until the swelling has subsided. Massage of such a gland should be withheld for three to four weeks or longer after it has become normal in size.

A rather common error is to be stampeded into the belief of definite abscess formation and advise operation at which only a quantity of dark blood is obtained. Even in the absence of abscess these cases often have a high temperature (103° to 106° F.) for several days and a high leukocyte count (15,000 to 20,000) which often persists for a week or two after the swelling entirely has subsided. The temperature, however, rarely stays high more than five days unless there is an abscess formation. At times it subsides and then recurs. Under these latter circumstances there usually need be no doubt about abscess formation when the gland is palpated per rectum. If abscess formation does occur it is a far better surgical procedure to evacuate it through the perineum than to incise through the rectum or break it into the urethra.

The general treatment is that of any other febrile state and one does well to avoid efforts toward intravesical medication until the gland has become normal in size.

GONORRHEAL ARTHRITIS

Etiology.—As by far the large majority of our cases of gonorrheal arthritis occur among the poorly behaved, traumatically treated cases, it is safe to assume that the most potent precipitating factor is direct trauma to the infected structures. One should not assume, however, that just because a patient with gonorrhea has an arthritis that it is a gonorrheal arthritis, for it is not uncommon for patients with a previous history of focal infective arthritis to develop another attack at the onset of prostatic involvement by the gonococcus. In the absence of such a previous history the assumption of gonorrheal origin generally is warranted. To label arthritis gonorrheal simply because the patient once had gonorrhea is to lose sight of the fact that gonorrhea hardly ever lingers in the male more than a year or so, as well as the other far more common causes of arthritis.

Prevention.—The avoidance of direct trauma to the infected structures, of any surgical procedure however slight to these structures, insistence upon good patient conduct and resort only to the gentlest of treatment procedures, usually will practically obliterate gonococcal arthritis from the clinical picture.

Treatment.—If we may believe reports, and most of them seem trustworthy, it is in this complication that prolonged general hyperthermia registers its most striking success in the treatment of any phase of the disease. It is claimed that cure usually follows one treatment. The method, however, is not always easily available and many cases will have to forego its benefits.

When we turn to the question of other treatment we meet with a vast assortment of methods usually attended with the disappointments so common to such multiplicity. The most commonly used of these is rest in bed with restraint of the inflamed joint, usually by the use of a plaster cast. Some favor the intramuscular injections of foreign proteins. Some claim good results from small doses of gonococcal vaccines but the possibility of overwhelming the curative responses by vaccines

s a very real one. In the writer's opinion there is virtue at times in very small doses at the very beginning of an attack. Large doses used at any time probably account for some of the severe long-continued cases. The same applies with equal force to the Corbus-Ferry gonococcus filtrate.

It should be borne in mind that recovery from gonorrheal arthritis is just as much a matter of the building up of curative responses as is recovery from urethral gonorrhea. We have no quick, sure way to accomplish artificially what is really the patient's job. To overwhelm such a patient by the injection of gonococcal toxins or to roughly treat the lesions of the urethra and its adnexa during an attack of arthritis is to favor chronicity on the one hand and to favor both chronicity and extension to unaffected joints on the other. Seldom does one find in the entire clinical sphere of this disease a greater call for good judgment and gentleness of procedure.

FOLLICULITIS

Etiology.—Acute swelling of the urethral follicles is extremely rare in patients not subjected to traumatic treatment methods. Usually they follow the use of sounds, catheter irrigations or the instillating syringe during the course of gonorrhea.

Prevention.—The etiological factors readily show how the condition largely may be prevented.

Treatment.—It is far better to let nature deal with most cases of folliculitis rather than resort to efforts at intra-urethral surgical drainage. Almost invariably she does a better job, for resolution usually takes place. Local treatments to the urethra should be discontinued and heat applied two or more times a day, either by immersion of the penis in as hot water as can be borne for fifteen minutes, or a hot hip bath.

Where abscess formation really occurs and points toward the skin surface, incision should be made as soon as there is good reason to believe there is a true accumulation of pus. Such relief should not be withheld until the abscess has attached itself to the skin surface, for it usually spreads widely

before this takes place. In incising a follicular abscess care should be taken to make the skin opening far longer than is that into the abscess cavity and to pack the opening lightly with a gauze wick for a day or two. Otherwise the skin retracts and draws the external opening out of line with the internal causing subsequent drainage through a rather tortuous canal and greatly delaying recovery. To avoid the possibility of sinus formation all urethral treatment should be withheld at this time.

SEMINAL VESICULITIS

Etiology.—This is probably much the same as is the case with epididymitis. There is little clinical evidence of real value to suggest that gonorrhea affects the seminal vesicles in more than 2 per cent of the cases. This also has been fully discussed in the author's book on gonorrhea and cannot be elaborated upon here.

Prevention.—This is the same as holds for the prevention of epididymitis.

Treatment.—Where true gonorrheal seminal vesiculitis is shown to exist, by virtue of the fact that the patient experiences a real increase of urethral discharge containing gonococci after each involuntary seminal emission, the treatment consists in vesicular strippings per rectum. These never should be done until the local condition has subsided to a point where such manipulations become reasonably safe. Such drainage of the vesicle should be carried out three times a week instead of the twice a week advised for prostatic treatments. During the acute stages, however, heat is most beneficial and it should be carried out in the same way as has been advised for acute prostatitis. Diathermy has no advantages over heat thus applied and is not without danger because of the larger instrument that must be passed into the rectum.

Surgical intervention, such as seminal vesiculotomy or vesiculectomy is needed upon only the rarest of occasions. The writer has never had to advise it for a case he has seen in either private or dispensary practice.

COWPERITIS

Etiology.—This complication rarely occurs in the absence of urethral stricture, or high pressure irrigations or injections.

Prevention.—When resulting from the back pressure occasioned by urethral stricture it is usually in the type patient who has wilfully neglected the dilatations that have been advised, a thing not to be laid against the medical profession. On the other hand, the profession must share some of the blame for those few cases resulting from the forcible introduction of fluids into the urethra. That part of the picture we can obliterate by gentler methods of treatment.

Treatment.—The treatment almost always is surgical, for it is rare for a compound racemose of this type to fail to undergo abscess formation when infected by the gonococcus. Pointing, as a rule, toward the perineal skin surface on its own side of the bulbar urethra the condition usually is easy of diagnosis. Particularly is this so if grasped between the index finger in the rectum and the thumb on the external perineal surface.

Incision should be free and a small wick should be placed for drainage to prevent premature closure of the incision as the swelling subsides. In fact, it is well to keep up drainage for considerable time to avoid chronic infection of the gland. Chronic cowperitis sometimes follows infection without abscess formation. Such patients usually have a slight gonococcus-laden discharge for a long period of time. Normally Cowper's glands cannot be felt, so that any palpable swelling at the usual site of the gland should be considered pathological and treated. Frequently digital kneading of the palpable gland at the same time that the prostate is massaged is followed by cure. At times failure attends and it is then justifiable to remove the glands surgically, a procedure that presents little difficulty to either the surgeon or the patient.

MARKED INDURATION OF THE CORPUS SPONGIOSUM

Etiology.—This rather common forerunner of stricture formation almost invariably is due to urethral trauma either

by instruments, strong chemicals, masturbation or sexual intercourse during the acute stage of the disease.

Prevention.—This is obvious.

Treatment.—The local application of heat as heretofore advised is our best mode of treatment. Otherwise no local measures should be resorted to until the swelling has softened. Sedatives and the usual measures for the prevention of erection with its attendant chordee also are indicated.

LYMPHANGITIS AND DORSAL PHLEBITIS

Etiology.—These are almost always due to local trauma and are easily prevented by its avoidance. They are extremely rare in the usual run of office patients and far more common among the more poorly behaved group that attend dispensaries.

Treatment.—Practically always they clear up promptly on the use of heat and protection from further injury to the organ.

INGUINAL LYMPHADENITIS

(Gonorrheal Bubo)

Etiology.—The milder grades occur in almost every case of acute gonorrhea. The more pronounced grades usually are found in the patients with lymphangitis, phlebitis, phimosis and paraphimosis.

Prevention.—This rests in the avoidance of external trauma to the penis and proper cleansing of the preputial sac.

Treatment.—As the condition hardly ever eventuates in abscess formation but usually subsides within a few days no treatment is needed.

INFLAMMATORY PHIMOSIS

Etiology.—This is caused by the same things that determine the advent of phlebitis and lymphangitis and most commonly results from them. At times it is due to lack of cleansing of the preputial sac in the presence of urethral discharge and is associated with a balanoposthitis.

Prevention.—This is obvious.

Treatment.—The condition usually subsides rather quickly under the application of heat by penile immersion or the hot sitz bath and irrigation of the preputial sac with 1:5000 solution of potassium permanganate solution. Where the prepuce can be retracted the use of a mild antiseptic dusting powder is of great benefit.

If concealed ulceration is suspected a few days of heat and preputial irrigation frequently will restore conditions sufficiently for the retraction of the foreskin to make dark-field study, which is imperative for every penile sore, easily possible within three or four days. One should not hesitate to do a dorsal slit, or, perhaps, a cautery circumcision as few things are more important than the discovery of syphilis in its dark-field positive seronegative stage.

GONORRHEAL PARAPHIMOSIS

Etiology.—Almost invariably this is due to direct trauma to the penis in the presence of rather a small preputial meatus and its prevention is obvious.

Treatment.—The foreskin should be replaced as early as possible to prevent induration and ulceration at the point of greatest constriction. In order to do this the glans penis should be grasped by the gloved fingers of one hand, while the other hand is used to encircle the swollen, misplaced prepuce. Gentle, continuous pressure should be made upon both structures until about all of the swelling is gone. The parts then usually are easy to place in their normal positions. To prevent subsequent retraction it is well to pass a strip of adhesive plaster along one side of the penis, over part of the preputial opening in such a way as to make it smaller, but not occlude it, and then down along the other side of the penile shaft. This should be left on for several days. In the presence of neglected paraphimosis with much induration it occasionally is necessary to incise the constricting band on the dorsum of the penis. If ulceration has taken place it is wise to attempt to sterilize the surface by the application of tincture of iodine before in-

cision of the constriction. Ulcerations of the glans penis from prolonged penile constriction usually heal promptly upon the use of an antiseptic dusting powder. Before this is used, however, a dark-field study of the ulcer fluid should be carried out.

PARAFRENAL SINUSITIS

Etiology.—These glandular structures get their infection from the preputial sac and not the urethra. The condition is most common in individuals with profuse urethral discharge and a redundant prepuce. It probably is not preventable. Abscess formation almost invariably takes place causing a swelling just to one or both sides of the preputial frenum.

Treatment.—About the best way to handle this condition is to grasp the top of the swelling with a small mouse-tooth forceps and snip off most of the covering area with scissors. This leaves an opening through which it is easier to carry out local treatments, whereas a small incision soon shrinks so that the opening cannot be found. Starting the second day after opening, 5 per cent silver nucleinate or some similar solution should be injected into the gland channel daily if chronic gonococcal infection is to be prevented. For these structures, like the para-urethral sinuses, commonly harbor the gonococcus for months or years unless they are thus treated.

COMMENT

In the above citations of treatments one is likely to miss a number of things that have been rather widely vaunted for the various complications of this disease. Vaccines and the Corbus-Ferry gonococcus filtrate have been slighted intentionally as things more likely to produce complications than to promote their cure when once established. Diathermy, even in epididymitis, has lost most of its friends. General, prolonged hyperthermias in complications other than arthritis is hardly warranted. I have a report of fulminating suppurations in the only 2 cases of epididymitis one worker placed in his heat cabinet, and the other complications hardly merit such

treatment, if, indeed, it would benefit them. Just what such treatments would do for that fortunately rare gonorrheal complication, gonococcemia, remains to be answered.

The injection of foreign proteins in all stages of gonorrhea in the male and its complications, with the possible exception of arthritis, has lived its little hour and gone where most good Arabs go. The same can be said of a host of other things and largely we have returned to those things that gave even our forefathers good results. This is not without its rewards, not the least of which is an attractive simplicity of procedure in the place of uncertainty and confusion. Also, it is not necessary that one should impoverish himself by the purchase of paraphernalia that, though dramatic, largely are not needed for the treatment of either this disease or its complications.

CLINIC OF DR. FREDERICK S. SCHOFIELD

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA

THE MANAGEMENT OF CHRONIC PROSTATITIS

THE management of chronic prostatitis is quite often a problem that puzzles the urologist as well as the general practitioner.

The prostate gland is so situated anatomically that its normal drainage is mostly "uphill," contrary to the cardinal principle of "downhill" drainage for combating infection. The prostatic ducts and alveoli are lined with a single layer of columnar epithelium which is especially susceptible to infection and the external secretion, rich in lecithin, an excellent medium for almost any bacterial growth. Thus it will be seen that in prostatitis we are faced with the problem of treating not only an infection, but one that has been implanted in a most favorable soil. It may seem a trite statement to say that the treatment of chronic prostatitis depends upon the etiology of this infection but unless the many varied causative factors of prostatitis are evaluated and reviewed any haphazard treatment must be doomed to failure.

By far and large the greatest number of prostatic infections are postgonorrheal in origin. This ever prevalent disease affects from 75 to 85 per cent of the male adult population of the United States and is our third most prevalent infection, being exceeded only by the common coryza and measles. Gonorrheal prostatitis is always a complication of specific posterior urethritis. In gonorrhea the incidence of posterior involvement varies greatly with different clinicians. The limitation of gonorrheal urethritis to the anterior urethra

varies greatly according to different observers and to the type of cases treated. Dispensary patients usually have a tremendously high incidence of posterior urethritis due to lack of patient cooperation and also to the fact that daily treatment is not possible. In private practice the limitation of gonorrheal urethritis to the anterior urethra should show much more favorable results. Nevertheless there will always be an irreducible number of cases in whom a posterior involvement is inevitable.

The diagnosis of the early gonorrheal prostatitis should not be difficult. There is always an antecedent attack of specific urethritis accompanied by symptoms of dysuria, frequency, urgency or nocturia, all cardinal symptoms of posterior urethritis. Prostatic infection follows in every case of posterior urethritis. The gonococcus may be demonstrated in smears of the prostatic secretion of early prostatitis.

Here an important warning must be given as to when it is safe to massage or express secretion from a gonorrheal prostate. No digital manipulation should be attempted until the acute infection is entirely subsided and the voided urine is clear except for the presence of pus shreds. A safe method of avoiding complications is to withhold massage until the urine has been clear from ten to fourteen days and there is no reaction to posterior irrigation. Then the first attack on the prostate gland should be made with extreme gentleness, making no special attempt to obtain the secretion until it is seen that massage does not cause an acute exacerbation.

In "old" cases of gonorrheal prostatitis the discovery of the gonococcus is extremely difficult and there is always the probability that the specific organism has been overcome by an acquired immunity and that the infection is prolonged by a secondary bacterial invasion. Gonococcus carriers are rare in the male and persistent positive bacterial smears are usually the result of obvious clinical lesions.

The history varies greatly in prostatitis that is diagnosed from three or more years after an acute specific urethritis. There may be a period during which the patient indulged

liberally in alcohol and intercourse, having been pronounced cured of an original infection, then for no definite reason has a recurrence of prostatitis manifested by a urethritis or prostatic smear containing an excess of leukocytes. It is practically impossible for a host to the gonococcus to indulge in alcohol or intercourse without exacerbation of infection and any bizarre history indicates a lighting up of a chronic nonspecific infection or an untruth on the part of the patient, usually a married man.

It is difficult to demonstrate the gonococcus in prostatitis coming to treatment at a late period following the primary attack. Smears may be negative and cultures of prostatic secretion are unsatisfactory because other bacteria will outgrow and mask the gonococcus even if it is present. The complement fixation test may be of value but it is difficult to procure a satisfactory antigen and there is doubt concerning the period that this test is positive following the subsidence of specific infection.

Treatment of specific prostatitis should be begun with extreme caution and it is a safe rule that if doubt exists, then prostatic massage should be deferred. Prostatic massage accomplishes several things, including digital expression of secretion and pus, establishment of increased drainage and improvement in local circulation by relieving congestion.

The application of a mild antiseptic solution to the urethra is desirable in cases of recent infection. This may prevent a recurrence of urethritis from a new implantation of organisms expressed from the prostate gland. Potassium permanganate solution in strength varying from 1:8000 to 1:16,000 (1 to 2 grains in a quart of water) is quite satisfactory.

After voiding, the urethra and bladder should be irrigated with warm potassium permanganate solution two or three times and some of the drug be retained in the bladder by the patient. Massage should follow immediately and then the bladder emptied by voluntary urination to wash away the expressed pus and bacteria. Material for bacteriologic and microscopic examination may be obtained after massage.

Although the technic of prostatic massage is simple it might be well to remember that roughness will result in complications. Prostatic stroking should be done in the vertical plane and the midline touched only at the termination of a treatment and then but lightly to obtain a specimen. Massage using a horizontal stroke may force infectious material into the ejaculatory ducts. This often results in an acute seminal vesiculitis and epididymitis for which the physician alone is to blame.

Fig. 2.—Direction of the stroking of the prostate gland. By leaving the midline strokes until last the discomfort is reduced to a minimum and is at the end of the treatment. (Pelouze, "Gonorrhea in the Male and Female.")

The extent of each treatment of course varies. Patient tolerance should be considered but in most cases no subjective discomfort is experienced after the first few massages. Each lateral lobe of the gland should be massaged until a definite emptying is felt which usually requires about ten strokes on either side.

Such treatment should be carried out twice a week. The importance of regularity should be impressed definitely upon the patient. Massage at weekly or longer intervals will never

cure prostatitis and more frequent treatment than at three- or four-day intervals may prolong the infection by the inflicted trauma. Fortunately gonorrheal prostatitis, under proper patient control and proper therapy, will readily respond and a cure should be effected in from three to four months.

The diagnosis of cure in these cases may be made by microscopic examination of the prostatic secretion. Specimens

Fig. 3.—The microscopic appearance of normal prostatic secretion. The laminated bodies are corpora amylacea. The other large cells are prostatic granule cells. The next smaller are polymorphonuclear leukocytes in normal numbers. The remainder of the field is studded with lecithin bodies which are characteristic of this secretion. (Pelouze, "Gonorrhea in the Male and Female.")

should be examined under the high dry power of the microscope. Clumped leukocytes or an average of more than 8 to 10 per high dry-power field is an indication for further treatment. It is difficult to find the gonococcus in smears in the later stages of this infection but these organisms will not remain in the prostate gland without producing a leukocytic response. Therefore if no pus is found in the prostatic secre-

tion for three consecutive smears a diagnosis of cure may be made provided that other foci of infection are eliminated.

Vaccines are of no value in the treatment of gonorrheal prostatitis.

Short-wave diathermy has not had sufficient clinical trial for its proper evaluation. If heat that is controlled properly and not destructive can be limited to an infected gland some beneficial results might be secured. However, it must be re-

Fig. 4.—Prostatic secretion composed almost entirely of granular debris. A restudy within a few days generally reveals a large amount of pus. (Pelouze, "Gonorrhea in the Male and Female.")

membered that columnar epithelium such as found in the prostate gland has a lower thermal death point than that of the usual invading bacteria.

The nonspecific or nongonorrheal prostatic infections include a large group of mixed and often obscure etiology. Careful studies must be made and the treatment here often calls for long and varied therapy.

Commonest of all nonspecific infections are those in which

the prostate becomes secondarily involved and remains so until the original focus is eradicated. The symptoms may be those of focal infection such as general arthritis, spondylitis, iritis or iridocyclitis and almost any diseased condition from "spring fever" to brain tumor. In other instances symptoms point directly to the prostate as evidenced by chronic urethritis, pus shreds in the urine, or perineal and low lumbar pain.

Fig. 5.—Prostatic secretion of a poorly draining infected gland. The scarcity of lecithin bodies in such secretions is very striking. As the leukocytes decrease in number these increase. (Pelouze, "Gonorrhea in the Male and Female.")

These statements should not indicate that prostatitis is the source of all disease, but that the study of any case in which focal infection might be suspected should include a thorough investigation of the prostate and its secretion. A study of cases in consultation practice will reveal that numerous patients have had exhaustive studies and prolonged treatment without benefit until chronic prostatitis has been diagnosed and cleared up.

A constant and usual finding in secondary prostatitis is that the gland will improve and that pus will diminish under treatment. However, a vacation from massage or a flare up of original focus results in reinfection. The very recurrence of a chronic prostatitis is evidence enough that it is a secondary infection.

Dental apical infection or the presence of nonvital teeth are often a primary focus of secondary prostatitis. The dental

Fig. 6.—A prostatic secretion showing a slight tendency toward clumping of the leukocytes. Such a secretion is commonly seen and bespeaks poor prostatic drainage. It likewise is an intermediate picture evidencing improved drainage where previously there have been large clumps. (Pelouze, "Gonorrhea in the Male and Female.")

profession seem to be on the conservative swing of the pendulum. The radical tendency toward extraction of a few years ago seems to be now replaced largely by an attempt to treat abscessed teeth, rather than extract them. This may be successful in a few instances, but better and quicker results will be obtained in the presence of a prostatitis if all suspicious teeth

are extracted. Modern dental prosthesis is of such perfection that partial or complete dentures may be used and worn with comfort, thus overcoming any esthetic objections on the part of the patient.

If oral infection is allowed to remain, even under treatment, there is the possibility that it together with the secondary prostatitis may cause serious disease. Arthritis, iritis or any systemic complication may arise if any degree of infection persists.

Fig. 7.—Prostatic secretion from a badly infected nondraining gland. The leukocytes are closely packed, old, and on the verge of disintegration. Lecithin bodies are almost absent. (Pelouze, "Gonorrhea in the Male and Female.")

Next in frequency as a cause of prostatitis is chronic sinus disease and chronic tonsillar infection. Not every one suffering from either or both of these diseased conditions has a prostatitis, but if this latter infection is present then the former should be viewed with suspicion. Tonsillectomy is an operation performed by many physicians and not always with the proper skill. Small tonsillar tabs are enough to harbor

infection and a complete examination is necessary even with the history of a previous tonsillectomy. Tonsillectomy, of course, is indicated even if the amount of tissue to be removed is small.

The problem of sinusitis is not so clearly definable, especially in a region such as this where a high majority of individuals, more marked in heavy smokers, suffer a varying grade of "Philadelphia nose and throat." Sinusitis of definite and recurrent type should be treated either by conservative or radical means. The opinion of the otolaryngologist should be freely asked and his advice followed. It is difficult for a general practitioner or a specialist in another field to gauge the extent and effects of sinus disease. If chronic prostatitis exists the sinusitis should be considered a primary factor and treated until its effect upon the prostate can be ascertained. There is no question that there are some instances of sinus or other infection that have no bearing, other than coincidental, upon the course of prostatitis. However, a therapeutic trial should be given especially if no other primary focus is present.

Less common primary foci for prostatitis include the gastro-intestinal tract, the gallbladder and the skin. These are unusual but should be considered if more obvious etiologic factors are not evident. Chronic constipation may be a factor owing to faulty elimination. Cholecystitis may be overlooked in prostatitis but should be eliminated as a causative factor. Dermatitis of the pyodermic type always should be investigated if associated with a persistent prostatitis.

The scope of this paper does not include a detailed study of the conditions enumerated in the preceding paragraph. The diagnostic measures needed to implicate any one of them are involved but attention is called to these condition in any resistant case of prostatitis.

Local conditions in the urethra may cause a persistence of chronic prostatitis, either by interfering with urethral drainage or by a continued irritation. Strictures, either congenital or acquired, may be causative factors. Strictures of the anterior urethra and as far posterior as the bulbomembranous

junction are practically all inflammatory in origin arising as the result of gonorrhea or from the injudicious use of too strong antiseptics which destroy urethral mucosa. This is always followed by its replacement with scar tissue which ultimately contracts to form a stricture. Strictures in the posterior urethra are congenital valves usually arising from the cristae galliae and may cause varying amounts of prostatic and urinary obstruction.

Anterior strictures may be diagnosed by a bulbous bougie or sound while posterior strictures are found by visualization through a urethroscope or cystoscope. Dilatation should relieve anterior strictures while fulguration is necessary to cut away the congenital valves.

Urethral irritative factors include the lymphoid bodies of Pelouze, polyps and papillomata. Repeated local treatment may be required to remove these conditions. Endoscopic applications of 25 to 50 per cent silver nitrate will destroy lymphoid bodies and polyps. Papillomata may be removed more satisfactorily by fulguration.

There are certain sexual aberrations that result in a prostatitis due to the result of prolonged passive congestion. Adult masturbators usually have a chronic prostatitis in proportion to their efforts in their favorite pursuit. Coitus interruptus, or withdrawal before orgasm, is a popular method of birth control. This procedure results in prostatitis following the passive congestion of incomplete orgasm. Too frequent intercourse and coitus prolongatus are conducive to prostatitis because of prolonged congestive trauma to the prostate gland. The remedy in all of these instances is obvious.

Many young men present themselves with a nonspecific urethritis that is caused by a low-grade prostatitis. Here there is often a history of excessive indulgence in alcohol and sexual excitement with or without intercourse. If no primary focus can be found these cases clear up upon prostatic treatment and correction of their social habits. The treatment of chronic nonspecific prostatitis should be directed along various lines. Original foci of infection should be searched for care-

fully, and eliminated by the proper therapeutic procedures. The confidence of the patient should be gained in order to ascertain whether or not he is indulging in any practices which might retard his progress. Cystoscopy or endoscopy is indicated in all instances in which treatment response is tardy.

Prostatic massage, as outlined previously, should be carried out regularly twice weekly. Intravesical irrigation is necessary only in those cases in which a urethritis is present. The time element varies greatly. It is usual for a nonspecific prostatitis to be more resistant to treatment than a post-gonorrheal infection and no patient should be given a glowing promise of prompt cure. In spite of ideal treatment and the location and elimination of a definite causative factor, the persistence of prostatitis may exceed the anticipation of both patient and physician.

Vaccines, either autogenous or stock, produce varying results, exactly as in any other infection. Autogenous vaccines are to be preferred and should be used only in small doses to avoid the establishment of a prolonged negative phase. Vaccines prepared from cultures of staphylococci seem to produce the least favorable results. Those made from streptococci, colon and diphtheroid organisms seem to produce beneficial results in certain cases.

Nonspecific protein therapy has not proved of value in the treatment of chronic prostatitis.

Reports vary upon the efficacy of direct injections of bacteriocidal substances into the prostate gland by both the trans-urethral and perineal routes. The author has had no success with injections through the McCarthy pan-endoscope and Dr. Sterling W. Moorhead (personal communication) states that injections via the perineum have not resulted favorably. Other operators have been more impressed by these methods and have reported large series of cases treated by a direct method. Here the end-results have been satisfactory but the methods used have required hospitalization of the patients.

Summary.—Gonorrheal prostatitis responds well to proper treatment if the patient is cooperative.

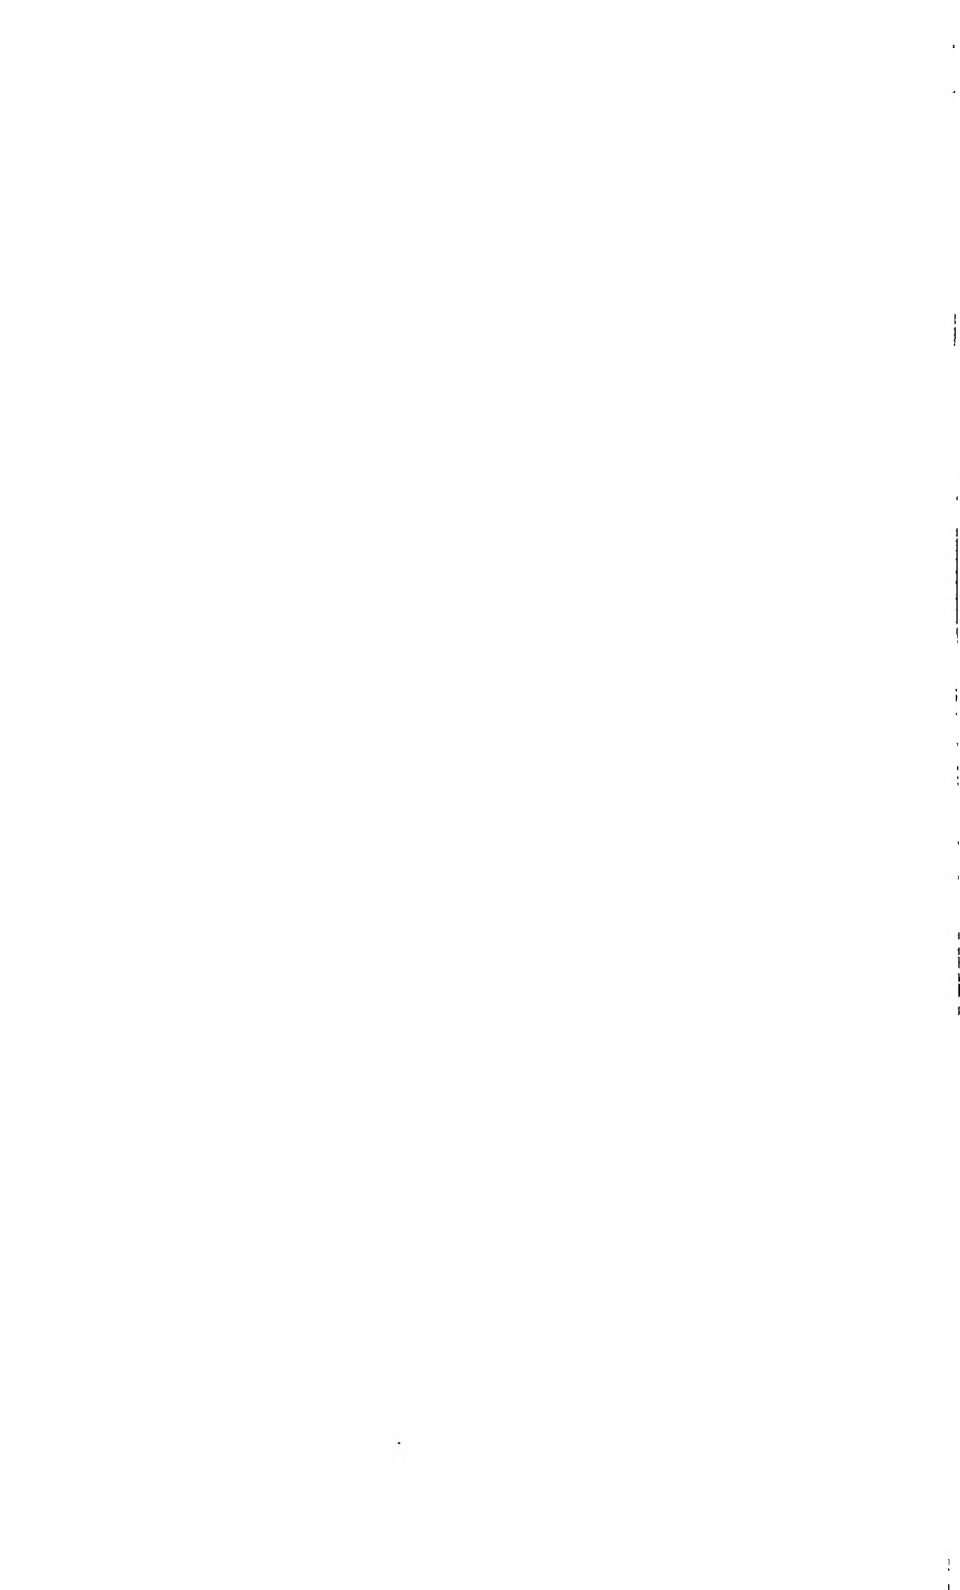

Many cases of prostatitis are due to secondary infection and will not respond unless the primary focus is eliminated.

Local pathology in the urethra may prolong a prostatic infection and should be searched for in recalcitrant cases.

The social and sexual habits of patients may produce or aggravate a prostatitis.

Chronic prostatitis requires a long course of treatment sometimes extending over a period of many months.

Some of the "newer methods" of treatment are not practical for general application.

CLINIC OF DR. HENRY K. MOHLER

JEFFERSON HOSPITAL

THE DIAGNOSIS AND TREATMENT OF THE MORE COMMON CARDIAC ARRHYTHMIAS

THE common disorders of the cardiac mechanism, although but symptoms, have come to be considered as much in detail as are clinical entities. That they are but symptoms must not be lost sight of in any discussion of the subject.

The normal rhythm of the heart originates in the sino-auricular node, which lies at the junction of the superior vena cava and the right auricle.

The node receives branches from the vagus and also from the sympathetic nerve fibers, the former the inhibitory influence and the latter the accelerating force. A normal balance between these two nervous influences results in a regular heart rate of 65 to 80 per minute in the adult.

The cardiac irregularities are the result of either abnormal impulse production or conduction. The more common irregularities encountered are:

First.—Sinus arrhythmia.

Second.—Premature contractions, also referred to as extrasystoles.

Third.—Simple paroxysmal tachycardia.

Fourth.—Auricular fibrillation.

Fifth.—Auricular flutter.

Sixth.—Heart block.

Seventh.—Pulsus alternans, also referred to as alternation of the heart.

Proper methods of treatment of the arrhythmias can only be instituted after the nature of the disturbance of the cardiac mechanism of the heart has been identified. In a clinical study of the arrhythmia, auscultation over the precordium yields more valuable information than palpation of the radial pulse. In the majority of the cases a clinical examination will lead to a correct diagnosis.

An electrocardiographic study always will give accurate information as to the nature of the irregularity.

The type of disturbance having been recognized it is of importance to determine whether it arises in the heart muscle or if it is due to extracardiac factors, of a nervous, chemical or physical nature.

If the arrhythmia has its origin outside of the heart muscle the underlying etiological factors are sought and if located are treated to eliminate the disturbance of rhythm.

If there is a reduction in the capacity of the heart for effort, the activity of the individual must be regulated, if possible, so as to avoid bringing on the attacks.

The use of stimulants, as coffee, tobacco, alcohol in a fatigued or diseased heart may cause an irregularity which can be avoided by discontinuing the use of the exciting substance.

Sinus arrhythmia is a type of cardiac irregularity, common in childhood, in which the heart rate usually increases with inspiration and slows with expiration. Less frequently it does not follow closely the respiratory phase. The impulses for contraction originate in the sino-auricular node but are not discharged regularly as is the case in the normal sinus rhythm.

It is very common in childhood, usually disappearing as the individual enters adult age. Very occasionally the irregularity does not disappear with adult life but persists or recurs from time to time with an increased instability of the nervous system.

In the past and at present, without the use of the electrocardiogram the diagnosis is frequently incorrectly made. Before the use of the electrocardiogram this arrhythmia, as all

other irregularities, usually was regarded as a manifestation of organic disease of the heart and treated as such.

Speeding up the heart by exercise may cause the irregularity to disappear. Such a condition is usually functional in origin unless there is a history of disease previously having been present capable of permanently affecting the heart or because of the improper use of digitalis. In the presence of signs or symptoms of organic heart disease this disturbance may be present, but is functional in origin. The important factor to recognize is that no restriction or treatment should be instituted because of the presence of his irregularity alone.

This arrhythmia is so marked occasionally and may not follow the respiratory phase, that clinically it resembles either auricular fibrillation, heart block or premature contractions.

Slowing of the rate can be brought to the point of producing weakness, syncope and dizziness, by the use of drugs such as digitalis and quinidine sulphate in full doses, hence their use is definitely contraindicated. The use of atropine sulphate $\frac{1}{64}$ grain (1 mg.) subcutaneously every three to six hours as needed, or ephedrine sulphate, $\frac{3}{8}$ to $\frac{1}{2}$ grain (20 to 30 mg.), or 10 to 15 minims or 1:1000 solution of epinephrine hydrochloride subcutaneously will usually increase the rate and cause the disappearance of symptoms which occasionally are due to the slow heart rate of sinus arrhythmia.

The very slow action of the heart in adults or children during disease or a surgical operation may be prevented by the hypodermic injection of 0.25 to 1 cc. of an aqueous solution of 1:1000 epinephrine hydrochloride. It is very unwise to restrict the activity of children in whom this form of cardiac irregularity occurs so commonly.

PREMATURE CONTRACTIONS (Extrasystoles)

The most frequent type of cardiac irregularity in the ambulatory adult occurs as premature contractions or, as they are also known, extrasystoles. Scarcely any individual fails to experience this condition at some time during life, even

though he is not conscious of its occurrence. The impulse for contraction in premature contractions arises outside of the normal center (the sino-auricular node). Organic disease of the heart often is not present. It must be excluded by a thorough investigation before assigning the cause of premature contractions as being functional in origin, or to a diseased condition arising outside of the heart or to toxic substances such as tobacco or coffee.

An individual may or may not be aware of their presence. Individual susceptibility is an important factor. The conditions of the nervous system, such as an instability brought on by emotional disturbances, susceptibility to tea, coffee, alcohol, tobacco, to fatigue, hyperthyroidism and intestinal disturbances are responsible or associated conditions. Premature contractions are often present in hypertension.

Premature contractions also have been termed, incorrectly, "dropped beats." Every second, third, or fourth heart beat at varying intervals may occur prematurely followed by a compensatory pause. These contractions are more likely to occur when the heart is beating slowly, during rest, and they frequently disappear with an increase in pulse rates such as produced by exercise. This observation usually will differentiate premature contractions from auricular fibrillation with a slow rate either at the bedside or in an ambulatory patient.

The occurrence of premature contractions in organic heart disease often precedes the onset of chronic auricular fibrillation.

If the premature contractions occur so quickly after a normal contraction so that the heart chambers have not been filled, then the premature contraction will not raise the aortic-valve leaflets. Under such circumstances no pulse effect is noted although the premature sound can be heard at the apex. A very slight pulse deficit then occurs and may be confusing if one does not think of it as occasionally occurring with premature contractions.

The treatment of extrasystoles consists in the elimination of the underlying diseased conditions and the removal or treat-

ment of other causes. The entire elimination or the use of smaller amounts of tobacco, tea, coffee and alcohol often aborts or prevents the occurrence of the irregularity.

The improvement of the digestion by discontinuance of overeating, eliminating highly seasoned food, the proper mastication of the food, the treatment of constipation, and by the use of physical exercises for those leading sedentary lives. The treatment of foci of infection has been successful in eradicating this disturbance.

Finally the use of sedatives, such as bromide of potassium, 10 grains (0.66 Gm.) three times daily, or the use of one of the barbituric acid compounds may produce magical effects.

Nothing will take the place of a period of rest for one hour once or twice during the day.

The use of digitalis is contraindicated unless congestive heart failure is present. Quinidine sulphate, 2 to 3 grains (0.13 to 0.2 Gm.) three times a day, has proved beneficial in eliminating premature contractions. They often disappear as quickly as they appeared, for no apparent reason.

SIMPLE PAROXYSMAL TACHYCARDIA

The etiological factors responsible for the attacks often go undiscovered and are those named in the discussion of premature contractions. Organic heart disease is usually absent. The person affected with the disturbance experiences a paroxysm of rapid heart action, beating regularly at a rate varying from 120 to 200 per minute. The attack starts abruptly and ends abruptly, and lasts from several minutes to several days. Occasionally an attack may continue from a week to six weeks. Frequently the longer attacks have been interrupted by a normal mechanism for a brief time only to have paroxysms recur again.

The rate of the heart at the beginning of the attack once set, does not fluctuate and is not affected by rest, exercise, posture and fever, such as does occur in ordinary tachycardia.

The rapid beating of the heart is usually readily observed over the precordium. The sensation of rapid cardiac pulsations

may be experienced, not only over the precordium but in some instances, more or less over the entire body.

The heart continues to beat rapidly and signs or symptoms of myocardial weakness do not appear until fatigue sets in, the onset which is determined more or less by the previous state of the heart muscle. A patient with mitral stenosis developing an attack of acute paroxysmal tachycardia would obviously be less able to effectively withstand an attack of myocardial fatigue, than an individual with a normal heart muscle.

Patients with prolonged myocardial fatigue as a result of paroxysmal tachycardia, become weak, develop an ashen gray color, congestion of the lungs, pulmonary edema and an enlarged liver. These signs and symptoms disappear very promptly with the cessation of the attack.

The treatment consists of therapy afforded during the attack and between attacks. Usually the paroxysms are of short duration and cease spontaneously and no treatment is needed.

The following plan of treatment is followed during the attack. Simple measures should be tried in the beginning after having endeavored to ascertain the cause of the attack. Inducing vomiting when the attack follows indiscretion in diet may end the tachycardia. The patient usually finds it more comfortable to be in a recumbent posture in quiet surroundings. An ice-bag over the precordium is helpful. Deep breathing with holding a long breath has been effective in ending many attacks. Counterirritation over the precordium by blistering, and mustard plasters is a useful remedial agent.

Occasionally a patient will find it more beneficial to walk or perform some slight bending, or leg- or arm-raising exercise and this may terminate the attack.

If these measures are unsuccessful in ending the tachycardia, then additional means should be instituted. These consist of stimulating the vagus nerves by making firm pressure first over the right carotid sheath in the neck for a period ranging from ten to sixty seconds. If pressure on the right side does not end the attack after one trial, then the same pro-

cedure should be undertaken over the left side of the neck. Pressure applied over the eyeballs with lids closed, one at a time, being firmly pressed inward may cause the attack to suddenly cease.

Quinidine sulphate by mouth in dosage of 2 to 3 grains (0.13 to 0.2 Gm.) every four hours has been effective in terminating the attacks. The idiosyncrasy to the drug should be tested before its use in full doses is attempted. Recently acetylbetamethylcholine has been used with success, beginning with the dosage of 20 mg. given subcutaneously every three or four hours.

In prolonged attacks, where congestive heart failure has resulted, bleeding and digitalization must be resorted to, but this rarely is necessary. Digitalis therapy as a general rule has not been successful in terminating these paroxysms.

When attacks occur frequently a careful history, a thorough physical examination and other tests should be obtained with a view of determining and eliminating the etiological factors.

The treatment between the frequently occurring attacks, for the purpose of preventing attacks, has not been uniformly successful. The continued use of 2 to 5 grains (0.13 to 0.3 Gm.) of quinidine sulphate three times a day has prevented frequent attacks, as has rarely full doses of digitalis.

AURICULAR FIBRILLATION

Auricular fibrillation is by far the most common irregularity found among the sick, of more serious import than some of the others and if recognized early and treated by the accepted methods responds in a very satisfactory manner, in a large number of the cases.

This disturbance is commonly associated with rheumatic fever manifestations (such as mitral stenosis), hypertension, coronary artery disease and hyperthyroidism, occasionally with unexplained conditions. It may also develop during acute infections such as tonsillitis, the grippe, acute bronchitis and pneumonia.

The diagnosis of this condition can usually be made at the bedside. The heart is irregular in rate, force and rhythm and usually rapid in the untreated case. Due to the number of small beats not reaching the radial artery there is a deficit in the number of pulse beats, being less than at the apex and this is known as pulse deficit. Adequate treatment causes the pulse deficit to disappear.

Exercise increases the pulse and heart rate and hence the degree of irregularity. Rest decreases these findings. The slower the heart rate when the patient is first seen the more difficult usually is the bedside diagnosis. An electrocardiographic examination may be necessary.

This condition is primarily one with no typical pathological picture by which it can be identified. In this disturbance, if it is of the chronic type (also designated as *pulsus irregularis perpetuus*, *delirium cordis* or the mitral pulse), the auricles are in a constant state of diastole, thereby not contracting as do the ventricles.

In the untreated case the heart ranges from 90 to 150 per minute. The guide to efficient treatment is the heart rate, not the pulse rate. The object sought for, in the treatment of chronic auricular fibrillation, is a heart rate, though irregular, ranging approximately from 70 to 80 per minute. Clinically the types of auricular fibrillation may be classified into (a) paroxysmal, (b) permanent or chronic type.

An attack of paroxysmal auricular fibrillation may suddenly cease if the cause is removed. Overexertion or excitement or indiscretion in taking food or alcoholic beverages, or in methods of living, especially in an older individual with arteriosclerosis, may bring on an attack. Rest with restriction in the diet and the treatment of gastro-intestinal disturbances may cause the irregularity suddenly to disappear.

In the paroxysmal type, digitalis and drugs, with like effects, probably have a tendency to prolong an attack. The drug most effective in this type is quinidine sulphate, 2 to 5 grains (0.13 to 0.3 Gm.) three or four times a day, if no signs of congestive heart failure are present.

Inasmuch as early hyperthyroidism may be accompanied by attacks of paroxysmal auricular fibrillation the possibility of it being responsible for the irregularity must be kept in mind even though the thyroid gland is normal in size and suitable treatment immediately instituted. A basal metabolic study will assist in the diagnosis. The chronic form seldom returns to normal rhythm and it is dangerous to attempt this step especially if congestive heart failure is present, because of embolic phenomena which may occur.

The purpose sought in treating chronic auricular fibrillation is to reduce the ventricular rate as counted by stethoscope over the heart to a rate ranging from 70 to 80 per minute. This can be accomplished in the ordinary case by giving 20 minims (1.2 cc.) tincture of digitalis or 2 grains (0.13 Gm.) of digitalis leaves three times a day. Ordinarily in one week with the patient at rest in bed with a favorable prognosis this result is achieved. Digitalis is continued in reduced dosage, the maintenance dose, to keep the heart rate within normal range.

If the patient comes under the physician's care in extremis and has had very little if any digitalis in the previous seventy-two hours, an intravenous injection of strophanthin, $\frac{1}{120}$ grain (0.0005 Gm.), repeated in two hours and again in four hours, quickly may slow the heart rate. It is important not to slow the heart rate below 70 per minute or to give digitalis sufficient to produce heart block or coupling of the beats. This is dangerous and may produce sudden death.

Urgent symptoms of rapidly failing heart may require that the equivalent of 24 to 48 grains (1.5 to 3 Gm.) of powdered digitalis leaves be administered in from 1 to 6 doses during the first twenty-four or forty-eight hours.

Two conditions occur particularly in older persons. (1) Auricular fibrillation with a normal heart rate without symptoms. To treat this type of auricular fibrillation with digitalis is unwarranted, contraindicated and may prove fatal. (2) The other type case is one in an elderly person with marked congestive heart failure, heart rate 70 to 80 per minute with

or without the use of digitalis. To further reduce this rate is exceedingly dangerous. The prognosis in this type case is very grave. Absolute rest in bed and the administration of some opium preparation is indicated.

After a patient with auricular fibrillation has a heart rate of 70 to 80 per minute while in bed a maintenance dose of digitalis must be determined, which is the amount of digitalis required daily to keep the patient free from symptoms and enable him to be up and about if possible. By this method of digitalis therapy he may carry on for years.

In marked congestive heart failure with venous distention and cyanosis, blood letting may be a life-saving measure. Auricular fibrillation with hypertension may be benefited by the restriction of fluid and salt intake, rest in bed and the use of sedatives in addition to slowing of heart rate by digitalis.

The auricular fibrillation associated with hyperthyroidism disappears in a very large percentage of cases after surgical treatment of the thyroid gland. If no marked congestive heart failure is present and if auricular fibrillation persists after thyroidectomy quinidine therapy will restore a large number to normal rhythm.

The limitation of the patient's activity to his capacity for effort without symptoms must be insisted upon.

AURICULAR FLUTTER

Auricular flutter is not a very common occurrence. This type of irregularity is usually a chronic condition, lasting for months when untreated. Occasionally it occurs in short paroxysms. It is usually associated with organic heart disease, rarely is it a functional disturbance. Elderly individuals with diffuse arteriosclerosis are subject to this form of irregularity and it is very closely allied to auricular fibrillation. Patients with flutter often display periods of fibrillation. During hyperthyroidism attacks of auricular flutter may alternate with fibrillation.

The auricles beat at a rate of 200 to 360 per minute with the ventricles responding usually at a regular rate of 80 to 180

times a minute, every second, third or fourth auricular contraction being blocked. The rapid pulsations in the veins of the neck are often noticeable as compared with the pulse rate or the heart beats at the apex, which are much less in number. The rapid pulse may be regular or irregular, due to the ventricle responding only to every second or third beat at different intervals.

Its presence should also be suspected if there is an approximately regular heart rate of 80 or more per minute, with many more venous pulsations noticed in the neck than at the apex of the heart. Exercise may suddenly double the heart rate.

This disturbance is treated as outlined for auricular fibrillation with the use of digitalis. The tincture in doses of 20 minims (1.3 cc.) or 2 grains (0.13 Gm.) of powdered digitalis leaves is given three or four times daily until the heart rate is about 60 or 70 per minute. As the pulse rate is slowed, often the auricles begin to fibrillate. This should be a sign to discontinue digitalis therapy for twenty-four hours, during which time the heart rate usually returns to a normal rhythm. Auricular flutter may again return and the same procedure with digitalis therapy should be repeated.

Quinidine sulphate is a remedy used to eliminate flutter and only is recommended when digitalis fails, on account of the possibility that it may produce dangerously high rates.

The paroxysmal type of auricular flutter is treated by rest and digitalis, according to the method employed in the chronic type of flutter. All other measures used in the treatment of auricular fibrillation will be useful in the therapy indicated for this condition.

HEART BLOCK

The heart block to be described is that form that usually can be recognized clinically as partial and complete forms. It is a serious condition of the heart and commonly denotes rather widespread degenerative changes in the myocardium, unless it be congenital in origin. It may be temporary in

or without the use of digitalis. To further reduce this rate is exceedingly dangerous. The prognosis in this type case is very grave. Absolute rest in bed and the administration of some opium preparation is indicated.

After a patient with auricular fibrillation has a heart rate of 70 to 80 per minute while in bed a maintenance dose of digitalis must be determined, which is the amount of digitalis required daily to keep the patient free from symptoms and enable him to be up and about if possible. The paroxysmal type of auricular flutter is treated by rest and digitalis, according to the method employed in the chronic type of flutter. All other measures used in the treatment of auricular fibrillation will be useful in the therapy indicated for this condition.

HEART BLOCK

The heart block to be described is that form that usually can be recognized clinically as partial and complete forms. It is a serious condition of the heart and commonly denotes rather widespread degenerative changes in the myocardium, unless it be congenital in origin. It may be temporary in

nature, due to changes in conduction tissues or from overdigitalization or from acute infection and rheumatic fever.

Occasionally the changes are limited solely to the conduction system without any symptoms of myocardial insufficiency becoming evident for years. This has been so in block which developed years after an attack of diphtheria damaging the conduction tissue, with no or only slight damage to the myocardium.

Those recognized only by the electrocardiogram—prolongation of the P-R interval and bundle-branch block are not under consideration in this discussion. They cannot be recognized by physical examination.

When every second, third or fourth contraction of the auricle is not followed by a ventricular contraction, partial heart block results causing a slowing of the heart rate and pulse rate of 35 to 50 per minute. When the auricles and ventricles beat independently of one another with a rate of usually less than 40 per minute complete heart block is present.

In partial heart block the slowed ventricular rate may return to normal under the influence of atropine and exercise, usually not so in complete heart block unless it be of the acute type. An electrocardiogram is very helpful and is the only final test in doubtful cases of heart block.

The treatment of heart block is dependent upon the recognition of the associated conditions and etiology. If the heart block follows an acute infection, such as acute rheumatic fever, an attack of acute tonsillitis, diphtheria or syphilis, the treatment of these conditions with rest in bed may restore the normal mechanism of the heart.

If heart failure develops in a patient at rest in bed because of partial heart block, digitalis must be used in suitable dosage, 10 to 20 minims (0.66 to 1.33 cc.) of the tincture or 1 to 2 grains (0.06 to 0.12 Gm.) of the digitalis leaves three times a day. Even though the heart block may become complete atropine sulphate, $\frac{1}{15}$ grain (0.008 Gm.) three times a day, has caused the block to disappear.

If syphilis is present it should be treated actively, although it frequently is not effective in the treatment of this block.

The slow heart rate of chronic block is not affected by fever, exercise and stimulants and this is a diagnostic point in differentiating it from a slow heart with normal mechanism.

The problems of treatment in complete heart block is often a great problem clinically, since in the condition the muscle as well as the conduction system is more frequently involved than in the conduction system alone. The complete block that follows acute coronary thrombosis often makes the prognosis more grave. The weak myocardium beating at half rate results in an inadequate circulation of the blood. Here absolute rest in bed, with the various drugs suggested may be tried as indicated by the condition or etiology to which it is related.

The Stokes-Adams syndrome in which convulsive features are present because of the pulse slowing to from 4 to 12 per minute requires the use of strychnine sulphate, $\frac{1}{80}$ grain (0.02 Gm.) hypodermically, or 4 to 8 minims (0.25 to 0.5 cc.) epinephrine solution 1:1000 given intravenously. If the heart ceases to beat the immediate injection of 0.5 to 1 cc. epinephrine solution 1:1000 into the heart muscle directly through the chest wall may be a life-saving measure.

Barium chloride, $\frac{1}{4}$ to $\frac{3}{4}$ grain (0.015 to 0.045 Gm.) by mouth three or four times a day, has been reported to increase the irritability of the myocardium and hence increase the rate of contraction. This experience has not universally been confirmed by those who have used this drug.

Other preparations recommended are epinephrine in dosage of 0.5 to 1 cc. (1:1000 solution) given hypodermically, thyroid extract, strychnine sulphate, digitalis, the nitrites and vasodilators, such as the theobromine compounds, of which the following enjoy a wide reputation in the treatment of coronary arteriosclerosis, theobromine, 5 grains (0.3 Gm.), theobromine sodiosalicylate, 5 to 7 grains (0.3 to 0.5 Gm.) and metaphyllin, euphyllin, aminophyllin, theophylline, $1\frac{1}{2}$ to 3 grains (0.1 to 0.3 Gm.) three times a day. Other compounds of theobromine are in use and may be helpful.

PULSUS ALTERNANS (Alternation of the Heart)

Pulsus alternans is said to be present when the heart is approximately normal in rate with the presence of a pulse in which alternate beats are strong and weak. This is a result of a large or small quantity of blood being driven into the arterial system at alternate contractions of the heart. The explanation of this phenomena is not satisfactory. It is seen in conditions of exhaustion of the heart muscle, particularly so in the elderly or in those with chronic nephritis, chronic myocarditis, hypertension, coronary artery sclerosis and angina pectoris. The condition is serious because of the disorders with which it is associated. Its presence is the sign of an overtaxed heart. It calls for the reduction of physical activity to within the capacity for effort of the heart and the treatment of the associated and underlying conditions. Fatigue of the normal heart muscle, as in prolonged physical strain in athletics and in lengthy attacks of acute paroxysmal tachycardia, also are causes of pulsus alternans. Slowing of the heart rate by rest causes this disturbance in the normal heart to disappear without any permanent or unfavorable effects.

It is diagnosed by taking the blood pressure by the auscultatory method. The larger beats coming through at the beginning of the systolic reading are one half of the pulse rate and as air escapes from the cuff with the lowering of the systolic level by 10 to 20 mm. of mercury, weaker beats come through, finally totalling the full heart rate.

No particular drug therapy is indicated. The underlying cause must be treated by the intelligent use of digitalis. Providing adequate rest for the heart muscle is of prime importance.

The alternate weak and strong beats may be heard when listening over the heart, especially if the breath be held in expiration. Palpation of the radial pulse in an easily compressible artery may disclose alternate strong and weak beats. In pulsus alternans the pulse is regular in rhythm with equal spacing between each beat, while in bigeminal pulse the beat

occurs in pairs with a compensatory or longer pause between the paired beats. The electrocardiogram does not disclose this alternation but a pulse tracing will definitely record it.

It is an important finding when present, confirming the presence of a serious heart lesion, especially when confused with other conditions capable of causing severe dyspnea such as emphysema.

DEPARTMENT OF PHYSICAL THERAPY, HOSPITAL OF THE
UNIVERSITY OF PENNSYLVANIA

PHYSICAL EXERCISE IN CARDIAC CONDITIONS

IN Europe physical therapy has been for nearly a century an important part in the treatment of heart conditions. It is true that this method of treatment in some quarters has been used in too enthusiastic a manner, or sometimes too much as a matter of routine with correspondingly disappointing results. However, when scientifically employed, it has been of much benefit in a large percentage of cardiac diseases. In this country the medical profession has been rather slow in adopting physical measures as a means of treating disturbances of the heart. Lately, however, there has been a decided movement in favor of this particular therapy in treating these conditions. Illustrative of this attitude is the statement of Dr. William D. Stroud,¹ President of the Pennsylvania Heart Association:

"At the risk of being considered a 'drug nihilist,' the author believes that drugs are seldom indicated in the treatment of cardiovascular disease until such disease has begun to produce the earlier signs of congestive circulatory failure. By this statement we mean to suggest that digitalis, nitroglycerin, and other drugs supposed to improve the efficiency of the circulation or to remove symptoms of loss of the circulatory reserve are actually contraindicated in the earlier stages of cardiovascular disease. My thought is that as morphine masks the symptoms of acute appendicitis, so digitalis in the presence of breathlessness or nitroglycerin in the presence of substernal or precordial pain removes the circulation's only method of

notifying the patient that too great a burden is being placed upon it. Thus, if these drugs are able to remove the 'brake'—that is, breathlessness or pain—the patient continues to place more of a strain upon his circulatory reserve than it is able to carry, and congestive failure or coronary occlusion may soon develop. Physical therapy, on the other hand, may help to remove some of the burden and also build circulatory reserve so that the patient may return to a modified daily routine without symptoms. Of course, the symptoms may ultimately return with such severity that medication is the only form of therapy which will bring relief."

Of the various methods of physical therapy there are two which are particularly useful in the treatment of cardiac diseases; namely, (1) hydrotherapy, and (2) mechanotherapy, *i. e.*, treatment by mechanical means such as massage and exercises.

In this article it is our purpose to discuss briefly the latter of these two modalities.

When outlining the treatment for a patient with cardiac disease we must consider which measures are indicated in the particular stage of the disease; measures that aid the heart in its work or those that stimulate the heart to increased activity.

Rest lessens the work of the heart. Analogous to any other overworked muscle, a weak heart is thereby enabled to recuperate and thus to increase in strength. Physical rest should be combined with mental rest, the latter being fully as important, if not more so, than the former.

Measures that facilitate the flow of venous blood to the heart aid materially in the work of the heart. The most important of these measures are massage, passive movements, and respiratory exercises.

By massage the blood is forced out of the veins by the moving pressure of the operator's hands on the soft tissues. Furthermore, as Pemberton² states, the capillaries in the treated area are dilated by massage. As a result of these two factors the resistance to the blood stream is decreased, and therefore the work of the heart lessened.

Passive exercises, by which is meant movements performed in the patient's joints by some outside force, usually a masseur, also lessen the work of the cardiac muscle and help in unloading the burden of the heart. This effect is due to the fact that passive movements bring about alternately a lengthening and shortening of the veins of the exercised part. Thus more blood is alternately sucked into the veins and pressed out of them in the direction of the right auricle, the venous valves preventing it from flowing in the opposite direction. In order that the exercises may be truly passive in character it is absolutely necessary that the patient and particularly the moved part is perfectly relaxed; otherwise a resistive rather than a passive movement will result with entirely different effect on the heart.

Respiratory exercises act also as an aid to the heart by assisting the circulation from the right to the left side of the heart. These exercises further aid the heart in that inspiration increases the velocity of the venous blood stream, and expiration assists the cardiac muscles in filling the arterial system.

Measures that chiefly increase the work of the heart are active exercises, *i. e.*, movements in which the patient brings his muscles into action by his own volition. These exercises may be in the nature of either free or resistive movements. In the former the patient himself performs the movement without assistance or resistance of the operator; in the latter the operator gives resistance to the movement performed by the patient. A special method of active exercises sometimes used in the treatment of cardiac diseases is the so-called "Stokes-Oertal Terrain Exercises." This method consists of walking out-of-doors; in the beginning at approximately an even level, then as the function of the heart improves, at a gradually steepening incline.

In the insufficiency of the heart is not too pronounced, free active exercises performed slowly and evenly with sufficient rest between each individual movement often produce more aid to the heart than stimulation to increased work. The explanation of this effect is as follows:

Active exercises, like passive exercises, bring about an alternating lengthening and shortening of the veins, with the same physiological effect. In addition, however, active exercises aid the heart in ways not produced by passive movements. The capillaries of the working muscles dilate; the same dilatation takes place in the cutaneous vessels all over the body.³ If the exercise is vigorous this latter effect is made visible by a general reddening of the skin. Furthermore, the contraction of the working muscles forces the blood in the veins of these muscles toward the right auricle. During the succeeding relaxation of the muscles the veins are filled again with blood. Finally, the respiratory movements are increased in depth and in frequency, and hence the pulmonary circulation is facilitated. The combination of all these factors brought about by active exercises naturally aids the heart materially in its work.

On the other hand, the increased amount of blood flowing into the heart, direct motor impulses, and probably chemical changes in the blood set up during voluntary exercise, all augment the activity of the heart. The more powerful the exercise, the greater is this increase in cardiac work.

Because of the afore-mentioned two-fold effect of active exercises upon the heart we are enabled by properly grading the exercises to produce a correct balance between the two opposite effects (*i. e.*, aid and increased work) so that we may meet the requirements of each individual case of cardiac disease. For this it is necessary, of course, that the heart have sufficient reserve power remaining to bear some increase in its work.

Let us now consider the therapeutic applications and the indications and contraindications of exercises in diseases of the heart.

Before a course of exercises, the patient should be thoroughly examined by the physician who, on the basis of his findings, then determines the type of movements, if any, suitable for the individual case. The physician should, in addition, carefully supervise the exercises throughout the whole

course of treatment. Medical supervision is particularly important during the first few weeks. During this period each exercise should, if possible, be under the guidance of the physician. Later on his presence during each performance of the gymnastic movements will be unnecessary, but he must keep in close enough touch with the case to be able to adjust the exercises according to the successive stages of the disease.

In the treatment of heart disease by medical gymnastics rest is a very important factor. Of course it would only aggravate the cardiac condition to treat with active exercises a patient whose heart has not sufficient reserve force to carry on his daily routine. Therefore we can see that more than the usual amount of rest, and, in some cases, a partial or total curtailment of the ordinary activity of the patient is a necessary complement to a program of gymnastic movements. As already mentioned, not only physical rest but mental rest is an essential element in the treatment of cardiac disease. Avoidance of responsibility, worry, and other emotional disturbances is therefore of great importance. It is difficult to either gauge the extent of these disturbances or relieve them if the patient continues to live in the environment which originally caused the mental strain. Hence the most satisfactory place for the treatment is in a hospital or sanatorium or at one of the various spas in this country or Europe.

During the execution of the exercises, the response of the cardiovascular system should be closely watched. If the exercises give rise to shortness of breath, palpitation, arrhythmia, or precordial pain, they should be discontinued at once or less vigorous movements substituted. Active exercises, even in a normal state of health, give rise to a temporary increase in the frequency of the pulse and a rise in blood pressure. If, however, the increase in the pulse rate and the rise in blood pressure last more than two or three minutes after the termination of the gymnastic movements they indicate that the exercises have been too strenuous for the heart. Less vigorous movements must therefore be substituted for them or they

The combination of all these factors brought about by active exercises naturally aids the heart materially in its work.

On the other hand, the increased amount of blood flowing into the heart, direct motor impulses, and probably chemical changes in the blood set up during voluntary exercise, all augment the activity of the heart. The more powerful the exercise, the greater is this increase in cardiac work.

Because of the afore-mentioned two-fold effect of active exercises upon the heart we are enabled by properly grading the exercises to produce a correct balance between the two opposite effects (*i. e.*, aid and increased work) so that we may meet the requirements of each individual case of cardiac disease. For this it is necessary, of course, that the heart have sufficient reserve power remaining to bear some increase in its work.

Let us now consider the therapeutic applications and the indications and contraindications of exercises in diseases of the heart.

Before a course of exercises, the patient should be thoroughly examined by the physician who, on the basis of his findings, then determines the type of movements, if any, suitable for the individual case. The physician should, in addition, carefully supervise the exercises throughout the whole

course of treatment. Medical supervision is particularly important during the first few weeks. During this period each exercise should, if possible, be under the guidance of the physician. Later on his presence during each performance of the gymnastic movements will be unnecessary, but he must keep in close enough touch with the case to be able to adjust the exercises according to the successive stages of the disease.

In the treatment of heart disease by medical gymnastics rest is a very important factor. Of course it would only aggravate the cardiac condition to treat with active exercises a patient whose heart has not sufficient reserve force to carry on his daily routine. Therefore we can see that more than the usual amount of rest, and, in some cases, a partial or total curtailment of the ordinary activity of the patient is a necessary complement to a program of gymnastic movements. As already mentioned, not only physical rest but mental rest is an essential element in the treatment of cardiac disease. Avoidance of responsibility, worry, and other emotional disturbances is therefore of great importance. It is difficult to either gauge the extent of these disturbances or relieve them if the patient continues to live in the environment which originally caused the mental strain. Hence the most satisfactory place for the treatment is in a hospital or sanatorium or at one of the various spas in this country or Europe.

During the execution of the exercises, the response of the cardiovascular system should be closely watched. If the exercises give rise to shortness of breath, palpitation, arrhythmia, or precordial pain, they should be discontinued at once or less vigorous movements substituted. Active exercises, even in a normal state of health, give rise to a temporary increase in the frequency of the pulse and a rise in blood pressure. If, however, the increase in the pulse rate and the rise in blood pressure last more than two or three minutes after the termination of the gymnastic movements they indicate that the exercises have been too strenuous for the heart. Less vigorous movements must therefore be substituted for them or they

must be entirely discontinued until the strength of the heart has increased.

As to the indications and contraindications of the various types and methods of physical exercises for cardiac conditions it is obvious that milder measures must be employed for patients with pronounced deficiency of the heart than for those in which the heart still possesses a certain amount of reserve power.

When the heart is so insufficient that it is unable to maintain a fairly normal circulation even during rest, or when the lack of cardiac reserve power gives rise to severe dyspnea during rest, the patient should naturally be confined to bed. Under these conditions only rest, gentle massage, and passive movements in a limited number of joints are indicated. Active exercises are absolutely precluded. The massage should consist of stroking movements from the periphery toward the center, performed gently, smoothly, and with slow even rhythm. The hands of the operator should be so molded as to conform everywhere with the contour of the part over which they are gliding. Most patients in this condition respond favorably to general massage and derive much benefit from it. Occasionally, however, we meet with cases who do not tolerate massage of the whole body. In these cases the manipulations should be limited to the extremities until the patient has improved sufficiently to benefit from systemic massage.

Passive exercises have a somewhat more pronounced effect on the circulation than massage. The necessity of complete relaxation on the part of the patient during these movements cannot be overemphasized. Like massage, passive movements should be given with a slow even rhythm, and the moved part must be well supported by the operator for the exercises to be of a truly passive character. During this stage of the disease all passive exercises which are anatomically normal to the joints should be given to the wrist, elbow, ankle, and knee. Each movement should be repeated approximately five times in the joints of the ankles and wrist, and two or three times in the elbow and knee.

The treatment should begin with two deep respirations and should progress in the following order:

1. Massage to one of the legs.
2. Passive movements to the same leg.
3. Two deep respirations.
4. Pause, one minute.

This procedure is then repeated successively to the other leg, to each of the arms, and finally to the trunk. During the massage the patient must never be lying in a prone position as this position would prevent the patient from breathing freely.

When the most severe symptoms of insufficiency have been overcome, the pressure of the stroking movements should be increased. Furthermore, "kneading" to the arms and legs should now become a part of the treatment. This "kneading" is performed as follows: the operator with his thumb abducted as far as possible from the other fingers grasps the patient's extremity between his hands, and massages with gentle circular movements the arm or leg so that the soft tissues move with the excursions of the operator's hands. In this form of massage it is necessary that the "kneaded" parts of the extremity be only slightly lubricated, if at all, for otherwise the operator's hands would merely glide on the surface of the patient's skin, and the effect on the underlying soft tissues and the blood vessels contained in them would be so slight as to be of no or negligible therapeutic value.

The patient is now also able to bear passive movements in the hip and shoulder joints as well as passive flexion and extension of the trunk.

These exercises are described as follows:

- (A) Rotation of the extended leg to right and left.
- (B) Raising and lowering of the extended leg.

(C) Raising the thigh forward-upward toward the trunk with simultaneous flexion of the knee and hip joints, followed by lowering of the thigh with extension of the hip and knee joints. In this exercise the operator, standing at the side of the patient, grasps the sole of the patient's foot with one of his hands (if the right foot, the right hand should be used, if the

left, the left) and places his other hand back of and just below the patient's knee. With his hands thus placed he moves the thigh of the patient up and down.

(D) Abduction and adduction of the extended leg.

(E) Circumduction of the leg. In performing this movement the operator stands and places his hands as in exercise C. With the hand placed back of the patient's knee acting as a guide and the hip joint as a pivot to the movement, the operator moves the patient's knee in circles, upward, outward, and downward, while the foot moves in a horizontal, median plane, forward and backward. This movement is performed two or three times in one direction and repeated the same number of times in the opposite direction. At the beginning the circles described by the patient's knee are small in circumference. Later on, if the patient's reaction is favorable, the circumference can be increased.

Additional passive exercises for the arms are as follows:

(A) Rotation of the extended arm to right and left.

(B) Raising of the extended arm forward-upward, and then lowering it. There should be inspiration during the upward movement, expiration during the downward movement of the arm.

(C) Plane carrying of the arms. The extended arms of the patient are carried in front of the patient first inward, then outward—the arms being at shoulder level throughout the extended motion. Respiration as in B.

(D) Abduction and adduction of the extended arm. In the beginning the abduction of the arm should not exceed one half of the normal maximum range of this motion. Breathing as in exercises B and C.

(E) Circumduction of the arm. The operator stands at the side of the patient whose arm is flexed to a right angle. He grasps the arm in such a manner that his one hand holds the patient's hand, his other the patient's elbow. The arm is then moved in circles, two to three times in one direction, two to three times in the other.

In passive flexion-extension of the trunk, the operator stands at the right side of the patient and places his right hand under the left side and his left hand under the right side of the upper part of the patient's back. He proceeds to raise the patient's trunk to a vertical position, then slowly lowers it to the bed.

The various therapeutic elements comprising the treatment, *i. e.*, rest, massage, movements, and deep breathing, should succeed each other in the order previously outlined.

When the unilateral movements of the extremities cause no fatigue, the movements should be given bilaterally whenever that is technically practical. For example, instead of giving abduction and adduction to one arm at a time, both arms should be moved simultaneously. On the other hand, it would be almost impossible for the operator to perform adequately simultaneously circumduction of the patient's legs.

When the reserve power of the heart has improved so that the patient no longer suffers from shortness of breath during rest, but the insufficiency persists in causing dyspnea and abnormally high or prolonged pulse rate and blood pressure after slight physical exertion, active exercises constitute the most important element of treatment. The exercises, whether free or resistive, are performed progressively according to the amount of reserve power of the heart. It is of the greatest importance that the operator be constantly aware of the necessity of the correct proportion between the physical activity and the heart condition. Any definite routine or program of exercises cannot be given as they vary with each individual case; there must also be modification of the exercises in the event of unusual mental strain, lack of sleep, climatic conditions such as severe heat or humidity, which influence the condition of the patient. There are however certain definite rules which must be strictly observed in performing active movements:

1. There should be an interval of at least one hour between a meal and the exercises.
2. The progression should be from free active movements,

through a combination of alternately free and resistive movements, to entirely resistive exercises.

3. At first the patient should exercise only from a supine position. As the strength of the heart increases the exercises may be executed in a sitting position, and ultimately in a standing position. It is obvious that the several positions necessitate because of their very nature a limitation in the selection of exercises; *i. e.*, certain exercises cannot be performed from the horizontal position, others are impossible in the sitting position.

4. When the exercises are initiated they should be performed with one extremity at a time. When the reserve power of the heart permits, the extremities may move simultaneously, that is, both arms or both legs. At this time the trunk as well as the extremities may be exercised, but only certain movements may be permissible.

5. The exercises must not be repeated successively in the same part of the body. In the case of a unilateral exercise, a movement in one extremity should be followed by the same kind of movement in the corresponding extremity on the other side of the body. If the exercise is being administered bilaterally, a movement performed by the arms should be followed by a movement performed by the legs or the trunk. Although it is not permissible for an individual exercise to be repeated in the same part of the body during the treatment, the whole set of movements may be repeated if the patient's condition permits.

6. At the institution of the treatment, the exercises should be performed with a limited range of movement. The progression may be made gradually to the maximum range possible to the joint or joints involved in the movement.

7. Where the physician feels that the exercises should be administered with especial caution, an individual movement may be divided into sections: for example, the extended arm may be raised to an angle of 45 degrees, then rested, supported on the operator's hand: after a few seconds the movement may be continued to the shoulder level.

8. All exercises that expand the thorax should be accompanied by inspiration; all exercises that compress the thorax, by expiration. The patient should never be allowed to hold his breath during any exercise.

9. In certain types of cases, active exercises should be preceded by a brief general massage in order to facilitate the emptying of the veins and capillaries. This introductory measure is valuable chiefly at the stage of the cardiac condition when the reserve power of the heart is not yet adequate to permit the exercises to be taken in a sitting or standing position.

10. At the termination of the exercises the patient should take from 5 to 10 deep breaths while resting on his back.

Some additional regulations are necessary concerning the administration of totally resistive movements.

1. The operator should not grasp the patient's extremity, but merely exert pressure in opposition to the movement *in one direction only*. Otherwise confusion as to the intended direction of the movement is apt to arise in the patient's mind.

2. The force of gravity must be taken into consideration in offering resistance to the movements. This rule is especially applicable to exercises performed in a supine position. For example, in leg raising and lowering, less resistance should be applied during the upward movement than during the downward movement of the leg.

3. Each exercise should be followed by a pause of one to two minutes.

We will now proceed to a discussion of the treatment in cases where a somewhat greater reserve power of the heart exists. To this class belong, among others, patients who are able to engage in mild physical activities and who can take prolonged walks on the level without becoming short of breath, but who become dyspneic on participation in somewhat more strenuous physical activities or upon walking on an inclined plane.

At this stage resistive exercises constitute the most important element of treatment. More resistance should be offered to these movements than was indicated in the treatment

of patients in the group just discussed. Types of exercises demanding a relatively great increase in the expenditure of cardiac energy can be more freely employed, such as, trunk flexion-extension in forward-backward and lateral directions and arm lifting to above the horizontal level. However, the general rules and precautions outlined above concerning the administration of active exercises must be scrupulously observed.

Resistive exercises are contraindicated in certain pathological conditions. They are precluded in advanced arteriosclerosis because in this condition the blood vessels are unable to adapt themselves to the increased blood flow resulting from the augmented activity of the heart. Consequently the strain upon these vessels and the heart would become too great, and harm rather than benefit would result. A condition in which an acceleration of the blood current would tend to cause hemorrhage or increase a hemorrhage already existing is likewise a contraindication. Neither should resistance exercises be used in pronounced angina pectoris because of their tendency in that condition to bring on a severe cardiac attack. Naturally, the patient's general condition must be taken into consideration. It is obvious that all exercises are contraindicated in cases of pronounced neurasthenia and other conditions where rest is the supreme need.

Finally we will consider that group of patients who have a sufficient amount of cardiac reserve power to carry on the ordinary physical activities of their daily life and who experience shortness of breath, palpitation, and show abnormally high or prolonged rise in pulse rate or blood pressure only after relatively great physical efforts. Two methods of exercises are indicated at this stage, namely, resistive movements, and, under certain conditions, the so-called "Stokes-Oertel Terrain Exercises."

The resistive movements may now be employed with considerable resistance. In contrast to the rule in the stages previously described, each individual exercise may be repeated once or twice before the next movement is performed. As in

the other stages, it is often advisable to give the patient a brief general massage immediately before the exercises.

In the Stokes-Oertel method the patient walks out-of-doors with a slow, even gait. A deep inspiration is taken at every or every other step. In the beginning the walk should be short and should increase in length progressively as the heart improves. The walking must never cause dyspnea. If this unfavorable symptom should occur the patient must stop at once and rest until his breathing has returned to normal. Whenever possible benches where the patient may rest should be placed along the road. Furthermore, there should be markers at regular intervals the entire length of the path to indicate the distances to be covered. The walking exercises should begin on a horizontal level and increase gradually both as to distance and to incline.

The advantages and disadvantages of the Stokes-Oertel Terrain Exercises are described by Dr. A. Weber,⁴ of Bad Nauheim, Germany, as follows:

"The Oertel cure, although possessing undoubted advantages, is being used less and less. By this method the physical activity corresponds in a very high degree with the requirements of the case. Undertaken in a systematic manner these exercises enable the heart to do its work with less effort than an untrained heart.

"Another great advantage is that these exercises are undertaken out of doors. Hence, the patient's general condition is benefited by the favorable influence of air and light. The psychic influence is equally beneficial. In a successful Oertel cure the steady improvement in functional capacity is much more apparent to the patient than in other therapeutic methods. Nothing makes a more favorable impression on the mind of a heart patient than when he finds that he is able to walk a path which he could not have attempted before.

"Oertel obtained many good results with his cure. Now-a-days, however, many physicians do not use his method because under certain condition it may cause considerable harm. One danger is that the patient often does not realize that he

Positions in which the exercise may be performed

Supine.	Sitting.	Standing.
---------	----------	-----------

ACTIVE EXERCISES.

Suitable for the treatment of cardiac conditions.

I. Movements of the Leg

In the ankle joint:

1. *Ankle flexion-extension.*
2. *Foot rotation to right and left.*
3. *Foot circumduction to right and left.* If the patient is sitting the leg in which the movement takes place is crossed over the other leg.

In the knee joint:

4. *Knee flexion-extension.*

In the hip joint:

5. *Leg raising forward and lowering.*
6. *Leg raising backward and lowering.*

In supine or sitting position. Seen from above

7. *Leg raising forward-backward and lowering.*

8. *Knee abduction-adduction.* The knees are bent at right angles during this movement. In supine and sitting positions this movement can be performed bilaterally as well as unilaterally.

9. *Leg abduction-adduction.*

10. *Leg rotation to right and left.* If the patient is sitting he should sit close to the anterior edge of the seat of the chair, or with his legs supported in a horizontal position on the seat of another chair, as otherwise the performance of this movement is almost impossible.

In the knee and hip joint simultaneously:

11. *Knee raising forward-upward and lowering forward-downward.* In sitting position this movement should be performed with the patient in the same position as in Exercise. 8.

12. *Knee raising forward-upward and extension; knee flexion and lowering downward.* The patient first lifts his knee so that the thigh is nearly at a right angle to the trunk. From this position he then extends the knee. The knee is then flexed and lowered to its original position. In a sitting position the movement should start with the patient's legs supported horizontally in the same manner as in Exercise 10. During the movement of the active leg the other leg remains supported.

Positions in which the exercise may be performed.

Supine. Sitting. Standing.

ACTIVE EXERCISES.

Suitable for the treatment of cardiac conditions.

I. Movements of the Leg—Continued

13. *Leg circumduction.* With the knee bent at a right angle circular movements are performed upward, outward, downward, first in one direction then in the opposite. This is always a unilateral exercise whether the patient is supine, sitting, or standing. Furthermore, it cannot be performed as a resistive movement.

II. Arm Movements

In the finger joints:

14. *Finger flexion-extension.*

In the wrist joints:

15. *Wrist flexion-extension in palmar-dorsal direction.*

16. *Wrist flexion in radial and ulnar direction.*

In the elbow joint:

17. *Elbow flexion-extension.*

18. *Forearm rotation.* The arm is bent at a right angle in the elbow and held closely to the side of the trunk. In this position the forearm is rotated on its long axis to right and left.

In the shoulder joint:

19. *Arm raising forward and lowering.*

20. *Arm raising backward and lowering.*

21. *Arm raising forward-upward—lowering forward-downward.*

22. *Arm raising forward-upward, forward-downward—backward and downward.* Both Exercises 21 and 22 make a greater demand on the heart than Exercise 20 and should not be attempted unless the heart has a fairly good reserve power.

23. *Elbow flexion position arm abduction and adduction.* The arm is flexed at the elbow. In this position the arm is abducted upward to shoulder level, then lowered to the side of the trunk.

24. *Arm abduction-adduction.* This exercise which is performed with the arm extended makes a greater demand on the heart than Exercise 23.

Positions in which the exercise may be performed.

Supine.	Sitting.	Standing.

---	---	---

ACTIVE EXERCISES.

Suitable for the treatment of cardiac conditions.

II. Arm Movements—Continued

25. *Arm rotation.* The extended arm held at the side of the trunk is rotated first in one direction and then in the opposite.
26. *Elbow flexion position arm circumduction.* With the arm flexed to an acute angle at the elbow the patient performs circular movements with the elbow first in one direction and then in the opposite.
27. *Arm circumduction.* The extended arm performs circular movements forward-upward-backward-downward, then in the opposite direction, i. e., backward-upward-forward-downward.

27

In the shoulder and elbow joints:

28. *Arm flexion-extension forward—flexion-extension downward.* The arm is first flexed upward at the elbow joint. It is then extended forward in a sagittal plane, so that the hand is brought straight forward at shoulder level. In the next movement the arm is flexed in the same manner and then extended downward to the side of the trunk.
29. *Arm flexion-extension outward—flexion-extension downward.* This exercise is performed in the same manner as Exercise 28 with the exception that the first extension is in an outward instead of a forward direction.
30. *Arm flexion-extension upward—flexion-extension downward.* Same as in previous two exercises except that the first extension is in a straight upward direction.

Exercises 28, 29, and 30 being composed of four individual movements increase considerably the work of the heart. In cases where the heart has a fairly good reserve power they can be performed, but if the heart is lacking in that reserve power, a rest should be given between each movement. Exercise 30 because of the arm extension above the head makes a greater demand on the heart than Exercises 28 and 29.

III. Trunk Movements

31. *Trunk flexion forward-extension upward.* This

STANDING POSITION

31

SUPINE POSITION

Su-pine.	Stand-ing.	Sit-ting.	
			<p>III. Trunk Movements—<i>Continued</i></p> <p>in a standing position the patient should stand astride with his feet two feet apart. When performed in bed the operator should lift the patient to a three-quarter sitting position. From this position the trunk is raised actively by the patient to a nearly perpendicular position. During trunk extension the operator should give resistance to the movement until the trunk rests on the bed.</p> <p>If performed with the full range of movement this is a very strenuous exercise.</p> <p>32. <i>Trunk lateral flexion.</i> The trunk is flexed in the lumbar and to a slight degree in the thoracic spine first to the right, then to the left. In standing position the patient stands astride; in sitting position his knees are about two feet apart.</p> <p>33. <i>Trunk rotation.</i> From stride-standing or stride-sitting position the trunk is rotated on the longitudinal axis of the spine first to right, then to left.</p> <p>34. <i>Trunk circumduction.</i> From stride-standing or stride-sitting the trunk is moved in circles, forward-outward-backward, first in one direction, then in the opposite. This is a very strenuous exercise.</p>
—	+	+	
—	+	+	
—	+	+	

is undertaking too strenuous a task. A walk makes a far different demand on the heart in intense sunshine or when the atmosphere is excessively humid or a strong head-wind is blowing. If the patient becomes fatigued during his walk, the road home may result in profound exhaustion. Particularly dangerous is a terrain walk on which the patient is unaccompanied.

"In my opinion it is to carry caution too far to eliminate the Oertel cure because of these dangers. There is no objection to the terrain cure if its limitations are well understood. If the uphill climb is supervised by a trained person or by the physician himself, and if a conveyance is held in readiness at all times to bring the patient back from his walking exercise, there can be no danger.

"Indications are: cured or nearly cured insufficiency of the heart, obesity, myasthenia, and all types of severe anemia and kyphoscoliosis.

"Contraindications are: danger of embolism and apoplexy, aneurism, angina pectoris, and all pronounced congestive conditions."

CLINIC OF DR. CHARLES L. BROWN

DEPARTMENT OF MEDICINE, TEMPLE UNIVERSITY SCHOOL OF
MEDICINE, AND TEMPLE UNIVERSITY HOSPITAL

PREVENTIVE ASPECTS OF CARDIOVASCULAR- RENAL DISEASE

CARDIOVASCULAR-RENAL disease, as the term is used in this discussion, is a condition which is characterized by the clinical features of widespread vascular disease and frequently the organ distribution of the vascular changes especially provides disturbed function of the heart, kidneys, brain, and eyes. The cause of this disease is not known, but it is closely related to hypertension and arteriosclerosis. Hypertension is only a measurable manifestation of this disease. In the light of present knowledge it seems unlikely that a single agent is responsible as a cause. Several factors seem to play a part in the cause and development of this disease. I shall refer mainly to those factors that seem to be important in the rôle of the physician as advisor to the patient.

Although there is considerable variation in the clinical behavior of this condition, three stages of development may be apparent; first, the potential cardiovascular-renal patient; second, the stage manifested by periodic and fluctuating degree of hypertension, or constant hypertension, but without symptoms; and third, the stage of well established hypertension with a variable chain of symptoms often referable to one or more organs or systems. In prevention of the disease as an entity, attention is especially drawn to the first two stages, while preventive measures in the third stage must necessarily concern complications. However, many factors which contribute to the development of the disease no doubt will also

influence some of the complications, even though the disease is well established.

Since knowledge at present is not certain enough to anticipate which member of a "vascular disease" family will develop clinical manifestations based on indications such as highly nervous temperament, frequent epistaxis in childhood, or signs of vasomotor instability, it is very difficult to evaluate, and advise the potential patient who may develop cardiovascular-renal disease. An inaccurate guess only contributes further undesirable and unnecessary anxiety to the patient's already possibly unstable psychic pattern. It seems possible that the reaction of blood pressure to a standard stimulus of cold reported by Hines and Brown¹ may be helpful in anticipating those members of "vascular disease" families who may develop vascular disturbance. Their studies indicated "that this vasomotor reaction follows an inherited pattern and that excessive or hypertensive type of reaction occurs in the families in which there is a hypertensive diathesis." Much further study is necessary before knowing how to interpret the findings for general application. However, the physician can not disregard his responsibility in watching over his "vascular families." O'Hare, Walker, and Vickers² in surveying the histories of 300 hypertensive cases found in 68 per cent of these patients a history of apoplexy, heart disease, nephritis, arteriosclerosis, or diabetes in one or more members of the family, while such history of familial vascular disease was present in only 37.6 per cent of a control group.

A very important group of patients is comprised of those who have developed definite hypertension but are without symptoms, and to these the physician must be a wise counselor and advisor rather than only a prescriber of drugs. Too often we must realize that we have very little scientific information on which to formulate advice. The four cases described below are representative of some of the individual types in this group and serve to elaborate the clinical application of some of the principles concerning apparently significant etiologic factors.

Case I.—G. R. B., male, age thirty-nine. Weight 167. School teacher. Has never had any symptoms referable to hypertension, although he has been known to have high blood pressure for at least four years, first observed during an examination for insurance. Has had no treatment for this condition other than an effort to avoid overweight. Does not use alcohol or tobacco. Because of a blood pressure of "over 200" found recently during a "health examination" he comes for medical advice. No family history of vascular disease other than his mother's sister died of a "stroke."

Physical Examination.—Stocky, sthenic type, not fat. Eyegrounds show very early vascular changes consistent with hypertension. No hemorrhages. No exudate. Heart moderately enlarged, the left border of cardiac dulness being 11.5 cm. in the fifth interspace. Accentuation of aortic second sound. No murmurs. Normal cardiac rhythm and rate. No signs of congestive heart failure. Blood pressure 220/120. After thirty minutes' rest lying down, 196/118.

Laboratory Findings.—Urine negative for albumin. No casts found but an occasional red blood cell was seen in the sediment. Highest specific gravity obtained in a concentration test was 1.026. Blood urea nitrogen 15 mg. per 100 cc. Urea clearance test showed 74 per cent of average normal function. Blood Wassermann negative.

Case II.—H. G., male, age forty-one. Weight 195. Physician. Has never had any symptoms definitely referable to hypertension, although during the past two years he had noticed ease of fatigue which he attributes to overwork and anxiety. Constipation for past five years. For past two years his blood pressure has always been found to be elevated, usually 160 to 180 systolic and 110 to 120 diastolic. Smokes excessively. Uses alcohol moderately. No family history of vascular disease.

Physical Examination.—Stocky, sthenic type. Obese. Eyegrounds show early vascular changes consistent with hypertension. No hemorrhage or exudate. Heart border-line

in size, the left border of cardiac dulness being 10 cm. in the fifth interspace. Accentuation of aortic second sound. No murmurs. Normal cardiac rhythm and rate. No signs of congestive failure. Blood pressure 174/118. After thirty minutes' rest lying down, 170/116.

Laboratory Findings.—Urine negative for albumin, and no casts or red blood cells found in the sediment. Highest specific gravity obtained in a concentration test was 1.030. Blood urea nitrogen 14 mg. per 100 cc. Urea clearance test showed 94 per cent of average normal function. Electrocardiogram negative except for slight left ventricular preponderance. x-Ray studies of heart and aorta showed very slight widening of aorta and very slight enlargement of the heart. Blood Wassermann negative.

Case III.—M. T., female, married, age forty-five. Housewife. Has never had any symptoms definitely referable to hypertension, although she has had constipation for many years and recently has noticed ease of fatigue, attributed to overwork and anxiety. Since age of fifteen has had occasional "sick headache" similar to those suffered by her mother. These have been less frequent and severe in the last few years. She has been known to have hypertension for past two years, discovered by "health examination." No treatment other than avoiding excess of protein and salt in the diet. Recently because of the fatigue has been resting more. Smokes moderately. Uses alcohol moderately.

No pregnancies. Menstruation irregular and scanty for past year. Occasionally has "hot flashes."

Mother died of diabetes mellitus at age of fifty, and maternal grandmother died of a "stroke" at age of seventy-six.

Physical Examination.—Tall and normal nourishment. Eyegrounds show very slight vascular changes consistent with hypertension. Heart moderately enlarged, the left border of cardiac dulness being 11 cm. in the fifth interspace. Aortic second sound moderately accentuated. No murmurs. Cardiac rhythm and rate normal. No signs of congestive

failure. Blood pressure 190/110. After thirty minutes' rest lying down, 186/108.

Laboratory Findings.—Urine showed a slight trace of albumin, occasional fine granular cast and red blood cell (not catheterized). The highest specific gravity obtained in a concentration test was 1.029. Blood urea nitrogen, 11 mg. per 100 cc. Urea clearance test showed 98 per cent of average normal function. Electrocardiogram was negative except for slight left ventricular preponderance. *x*-Ray studies of the aorta and heart showed very slight enlargement of the heart and some enlargement and elongation of the aorta.

Case IV.—E. B., female, married, age thirty-five. Housewife. Has never had any symptoms referable to hypertension, and the permanent high blood pressure was discovered first following an automobile accident about one year ago; said to have been "over 200." However, just before the birth of her only child five years ago she was told that she had kidney trouble and high blood pressure and her physician contemplated the advisability of interrupting the pregnancy a little early, but did not do so. She had no convulsions and the baby was normal. She was advised to have no further pregnancies. At this time she has no symptoms but seeks a periodic examination and medical advice as to any treatment for the hypertension.

Both her mother and a maternal aunt died of "strokes" at the ages of fifty-two and forty-nine respectively.

Physical Examination.—Moderately overweight. Eye-grounds showed retinal arteriosclerosis characterized by generalized attenuation of the retinal arteries, more marked peripherally. There was some accentuation of the reflex stripe. There were numerous punctate degenerative areas in the retina associated with pigment proliferation. This picture suggested a previous toxemia of pregnancy which was associated with retinitis and terminated in residual progressive hypertensive vascular disease. Heart not definitely enlarged. Moderate accentuation of aortic second sound. No murmurs.

Cardiac rhythm and rate normal. No signs of congestive failure. Blood pressure 220/110. After thirty minutes' rest lying down, 210/110.

Laboratory Findings.—Urine showed a very slight trace of albumin, but no casts or red blood cells were found. Highest specific gravity obtained in a concentration test was 1.028. Blood urea nitrogen, 10 mg. per 100 cc. Urea clearance test showed 77 per cent of average normal function. Electrocardiogram negative except for slight left ventricular preponderance. *x*-Ray studies of the heart and aorta showed very slight enlargement of the heart and a slight degree of dynamic dilatation of the aorta. Blood Wassermann negative.

By this time all four of these patients know that they have high blood pressure, are still essentially free of symptoms, and have sought advice about getting rid of the hypertension or in what manner to conduct their lives to arrest the condition and avoid or prolong the time of appearance of the complications later in life. All, by physical examination and laboratory studies, already show evidences of generalized vascular disease with some indication of incipient cardiac or renal involvement, although little or no manifestation of functional disturbance. Cases I and II are about the same age, and have essentially the same body type, although one is obese, the other is not. Their occupations are quite different. Case III represents the so-called "menopausal" type, who is not overweight. Case IV represents the female type still in the child-bearing period, already having vascular damage. The physician must act as advisor and his instruction to the patient will involve diet, the use of alcohol, tobacco, tea and coffee, exercise and occupation, the importance of mental and physical rest, infection, drugs, and in recent times the consideration of surgical procedures.

DIET

Protein Restriction.—It has become fashionable to restrict protein to some extent in the diet of such patients, the commonly accepted reason being the possible nephrotoxic

effects of protein or the by-products of protein metabolism. In the absence of renal functional impairment the usual diet prescription allows about the amount of protein necessary for normal body metabolism, perhaps as much as 1 Gm. protein per kilogram of body weight, or in the average patient 60 to 75 Gm. of protein daily. Clinical investigation in an effort to obtain guidance in protein restriction has produced rather conflicting findings, at least results rather difficult to interpret and apply to the individual patient. The work of Newburgh and his associates has been outstanding in support of the contention that by-products of protein metabolism are nephrotoxic. Protein feeding experiments were carried out on rabbits in the beginning.³ An objection occurred in applying the results to man, because of the rabbit being herbivorous, and therefore not accustomed to animal food proteins, and also because the rabbit may be subject to a spontaneous nephritis not exactly comparable to the nephritis of man. Later studies by Newburgh and coworkers^{4, 5} were made on white rats, showing that an excess of protein may cause urinary abnormalities in this omnivorous animal, and furthermore the development of these urinary changes were dependent upon the amount of protein and the length of time such diets were given. In investigating the element in the high protein diet that might be responsible for renal injury Newburgh and Marsh⁶ by injecting various amino-acids intravenously into normal rabbits and puppies, demonstrated that arginin, aspartic acid, lysin, histidin, tyrosin, tryptophan and cystin were nephrotoxic. Jackson and Riggs⁷ fed high protein diets, using casein and egg white, to rats over a period of ten to twenty months, corresponding to about one third of the rat's life, and were unable to produce any renal changes diagnostic of nephritis. Addis, MacKay, and MacKay,⁸ also using rats, fed a diet containing 70 per cent protein or 1 per cent of cystin over about one third the rat's life, and were unable to demonstrate any pathological changes in the urine or kidneys. Although the experiments of these careful workers are not exactly comparable in every respect, one cannot feel at ease in

disregarding the positive results obtained by Newburgh and his associates. One should be cautious in applying findings in the experimental animal to the human; yet if an excess of protein or its metabolic by-products can produce renal injury in the rabbit, rat and dog it seems not improbable the same agent might be harmful to man. In interpreting such experiments one should not overlook the possible variation of vulnerability of the kidney to nephrotoxic agents in different species, and even in different individual members of the same species. Taking the urinary cast count as an index of nephrotoxicity, Brown and Englebach⁹ have demonstrated that the rat may take much more mercury per unit of body weight than man before showing urinary changes, and an occasional rat may be especially resistant to mercury. Furthermore when the rat is given tolerant doses of mercury over a long period of time the kidneys may show very little microscopic evidence of nephritis, although the urinary-cast counts during life may have been increased.

In investigative studies in man again we find somewhat conflicting reports. Squier and Newburgh¹⁰ fed high protein diets to patients with hypertension and observed the appearance of red blood cells and albumin in the urine. McCann and Keutmann¹¹ gave diets containing 75 to 200 Gm. of protein per day to four patients with latent or chronic active stage of hemorrhagic nephritis and observed no adverse effects. In spite of a liberal allowance of protein the hematuria was not increased and renal function as determined by the urea clearance test improved. However, in two of his patients an increase in proteinuria occurred when 150 Gm. of protein was given, but the renal function was not diminished.

Fat.—The possible influence of high fat feeding on the development of arteriosclerosis is not certain. Many have objected to the use of high fat diets in the treatment of diabetes in the fear of increasing this complication in these patients possibly already more susceptible to arteriosclerosis. However, those enthusiastic about high fat diets are far from convinced that arteriosclerosis is more prevalent among dia-

etics so treated for long periods of time. Much more clinical observation and pathological correlation will be necessary to settle this point. Most attention has been paid to cholesterol metabolic disturbance. Arteriosclerosis of the atheromatous type has been produced in rabbits by high cholesterol feeding,^{12, 13} yet in the human an increased cholesterol in the blood has not been found uniformly in patients with arteriosclerosis, and, of course, many patients have advanced arteriosclerosis with no deviation from normal of blood cholesterol. Again species susceptibility must enter into this problem, as the rabbit seems especially vulnerable, and similar experiments do not produce similar results in many other animals. As yet evidence from feeding experiments is not convincing that disturbed lipid or cholesterol metabolism plays any significant part in human arteriosclerosis. Page, Kirk, and Van Slyke¹⁴ in studying 16 cases of uncomplicated hypertension found no increase above normal range of concentration of total plasma lipids or of any of the lipid fractions.

Salt.—Allen¹⁵ in 1920 advised greater restriction of salt in the diet of hypertensive vascular disease, and since then this has become a part of the routine advice to such patients. Further clinical investigation by others¹⁶ has indicated that such rigid restriction is not necessary, and furthermore it is not clear that salt plays any significant part in vascular hypertension.

Total Calories.—The amount of food, and indeed the amount at any one time, probably is of as much importance as the excess of any one element. Reduction in weight is advisable for the obese and very large meals at any time are to be avoided because of the strain on the cardiocirculatory system. Although it is not clear that obesity causes cardiovascular disease, this condition appears especially prevalent in the overweight. Cases I and III should be advised to gain no more weight, and Cases II and IV should be advised to reduce. Potential cases of cardiovascular disease should be advised to avoid overweight.

The matter of diet instruction demands a great deal of

time from the physician, and in most instances it is not scientifically accurate, and frequently the patient cannot or does not adequately carry out even more liberal requirements. In the light of present knowledge the following instructions in diet will satisfy most clinical indications: (1) carbohydrate, fat, and total caloric intake compatible with normal weight; emphasis on small meals; avoidance or reduction of overweight. (2) Protein restriction to avoid excess, in the average case 60 to 75 Gm. daily providing the metabolic need. (3) Restriction of sodium chloride to avoid excess; this is difficult for the patient to measure, and usually is satisfactorily met by the instruction of "no added salt." (4) Studies in water balance rather point to the advisability avoiding excess of total fluid intake, about 2000 cc. daily being satisfactory for most patients.

TEA, COFFEE, ALCOHOL, TOBACCO

There is no convincing evidence that any of these agents cause hypertensive vascular disease and any contribution they make to the clinical picture is probably secondary. Therefore, forbidding their use as a preventive measure acts only in avoiding secondary effects, which vary widely in different individuals, some being more susceptible than others. The restless, nervous patient who is especially sensitive to caffeine will do well to avoid tea and coffee because of his nervous system rather than because of his cardiovascular apparatus. While alcohol probably does not cause cardiovascular disease the effects of alcohol make any more than its very moderate use highly inadvisable. The possible influence of tobacco on the functional capacity of the heart and the causation of angina pectoris in some individuals indicates a caution to any other than its very moderate use in these cases.

THE NERVOUS SYSTEM, OCCUPATION, REST, EXERCISE

The mechanism of the nervous system in the regulation of blood pressure has been investigated by many workers in recent years. So much information is available that correlation

and application of it to clinical problems is in a state of confusion. From the nervous system aspect the blood pressure level seems to depend upon a balance of the pressor influence of the sympathetic vasomotor component and the depressor influence of the parasympathetic vasomotor component. A disturbance of this balance favoring elevated blood pressure might be due to increased pressor effects or decreased depressor activity. A comprehensive understanding of this whole mechanism implies the relationship of many variables some of which are practically intangible. Nervous temperament, psychic pattern, emotional stress and strain, the nature of one's occupation, mental rest, the degree of equanimity concerning the unpleasant things in life, recreation, and even constitutional pattern, and the endocrine system, all enter into the final result of this balance mechanism. In the age group represented by the above cases occupations are likely already chosen and adequate training obtained, so that advising change of occupation should be attended with caution especially if livelihood is jeopardized. More often it is a matter of the patient adjusting his nervous mechanism to look upon the vicissitudes of his occupation with more equanimity, or lessening the nervous and mental load in some way or having more frequent rest periods and vacations. If one could recognize the potential cardiovascular case, one might be justified in advising some particular type of occupation for which he should train; at present it would be difficult to choose such an occupation, because we hardly know what the specifications should be. In advising patients we mention an occupation as free of nervous and emotional stress and strain as possible, and not too strenuous from a "muscular work" standpoint. Yet there seems to be every reason for such patients to have adequate exercise as long as there is no impairment of cardiac function. The patient in some way should realize that the exertion attended by dyspnea or precordial discomfort, or indigestion, is beyond wise tolerance. Adequate rest and sleep at night should be insisted upon, and frequently regulated rest periods during the day are advisable.

INFECTION

It is difficult to evaluate the incidence of infections in past histories of cardiovascular cases. Walker and O'Hare¹⁷ in surveying 400 cases of hypertension and 400 control cases without hypertension found no indication that previous infection played an important part in the cause of hypertension. During active infection of certain types, blood pressure may be elevated, in other types it may be lowered. No doubt the involvement of the kidney, as in streptococcic infections, or the adrenal in certain acute infections is an important factor in immediate blood pressure changes. In an occasional case the removal of a focus of infection lends a very favorable influence on an existent hypertension. The decision regarding removal of or attempting to clear up foci of infection should be reached in the same way in the hypertensive as in any other patient; it is the logical thing to do, but caution is urged in anticipating preventive or curative effect on cardiovascular diseases.

DRUGS

Little need be said here about drugs as preventive treatment, since at present we have no known drugs that actually prevent this disease. The drugs in use are numerous, yet carefully controlled clinical investigation has not indicated convincing evidence of their efficiency in significant permanent lowering of blood pressure when employed in usually safe clinical doses. Most of the drugs referred to are used in treatment after the disease manifests symptoms. Recently the report of Barker¹⁸ has revived an interest in the use of potassium or sodium thiocyanate in the hypertension of shorter duration in young individuals. The administration of this drug, to be entirely safe, must be carefully controlled by blood thiocyanate determination. While such cases as described above might be considered for this therapy, there is no evidence of thiocyanate being a preventive, and the hazard of toxicity makes its use in general inadvisable. The possible relationship of the endocrine glands to hypertension is brought up in Case III in that the patient is in the menopause. Al-

though the ovaries, pituitary, adrenal or thyroid may have some influence on cardiovascular-renal disease there is no convincing evidence that available substitution endocrine therapy has significant preventive influence on the condition. On the whole sedatives, such as phenobarbital, are likely to be more helpful because of their influence in quieting a responsive nervous system.

SURGICAL TREATMENT

In recent years much attention has been called to various surgical procedures involving the sympathetic nervous system. Recently the results obtained by Peet¹⁹ and his associates in performing greater splanchnic nerve trunk resection has seemed encouraging, and especially so since most of his patients were in an advanced stage. However, experience with this kind of treatment must be considered still in the developmental and experimental stage. The criteria for suitable selection of cases are not established, and since knowledge concerning the sympathetic nervous system is in such a state of incompleteness and confusion, a very conservative attitude should be displayed in advising cases similar to those described above.

PREGNANCY

Pregnancy provides a great hazard to the hypertensive woman, and the avoidance of pregnancy or its interruption constitute most important preventive measures in such patients as represented by Case IV. The observance of this principle may give these patients years of useful and comfortable life. Eyeground examinations are of the greatest importance in these cases. Hallum²⁰ has pointed out that if retinitis occurs as a part of hypertensive toxemia before the twenty-eighth week of pregnancy the patient is almost certain to develop permanent vascular-renal injury.

CLINIC OF DR. A. M. ORNSTEEN

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA

INCIPIENT PARKINSONISM: DIAGNOSIS AND TREATMENT

PRIOR to the advent of acute epidemic encephalitis twenty years ago and its subsequent chronic ravages within the central nervous system, paralysis agitans occupied a quiet reserved place in the organic neurological scheme of things. It cropped up every once in a while in the latter decades of life and was recognized by the characteristic postures, attitudes and pill-rolling tremor. Its inception was not spectacular, its course insidiously progressive with increasing motor disability and tremor, hence the name paralysis agitans. Occasionally one would choose the name of Parkinson's disease in preference to the word paralysis out of respect for the unfortunate victim's feelings. Thomas Parkinson, English physician, formulated the symptom-complex of shaking palsy in 1817. For many years it was considered to be a functional disturbance of the central nervous system and treated as a neurosis until the pathological involvement of the lenticular nuclei was recognized and well established. It has been considered to be an idiopathic disease with premature disintegration of the ganglion cells of the globus pallidus except for the occasional case occurring in cerebral arteriosclerosis with softening in the region of the basal ganglia and in rare instances of tumor formation and syphilis involving the same area of the brain.

Much to the surprise and bewilderment of clinicians the great pandemic of influenza and the shortly following epidemics of acute encephalitis left in its wake numerous victims

with nervous manifestations suggesting paralysis agitans, yet differing in some respects either in the absence or predominance of one or the other characteristic features of paralysis agitans. Hence the term "parkinsonism" was applied to these postencephalitic cases. For a few years the diagnosis of postencephalitic parkinsonism was made only when the patient with rigidity and tremor gave a history of having had an attack of acute epidemic encephalitis. With increasing experience it was soon learned that the chronic manifestations of epidemic encephalitis could develop without a recognizable antecedent attack of the acute form. The incidence of the parkinsonian syndrome rapidly increased and observers became acquainted with a great variety of combinations of symptoms, some more or less fragmentary, until the symptom-complex was being diagnosed on the basis of a few fragments of the previously required diagnostic whole.

Aside from the exceptional type of acute parkinsonism, the development of the disease is usually insidious and one may correctly speak of the very earliest stage in the development of the syndrome as incipient parkinsonism. For obvious reasons the clinician strives to perfect himself in recognizing all pathological processes or clinical conditions in their incipient stages and it is with this in mind that the present paper is written. In preparing a digest of the initial symptoms and signs of the incipient stage of parkinsonism 100 private case records were selected representing patients varying in age from three to fifty years. Only 57 per cent of the patients either gave a history of having had sleeping sickness or described an acute illness strongly suggestive of that disease. Of the other 43 per cent a number of patients made mere mention of having had the "flu" or not at all. Complete recovery from the acute disease is frequently reported but just as often the patient is left with one or more residuals such as a change in the sleep rhythm from complete inversion (nocturnal insomnia and diurnal somnolence) to simple restlessness at night; ready fatigability, exhaustibility of concentrative powers, fluctuation of emotional tones or a group of physical and mental symp-

toms constituting a veritable psychoneurotic state which may last many months to several years. This is the interval period between the acute attack and the appearance of early parkinsonian manifestations, or it may constitute what might be called the period of invasion when the disease begins without an acute attack of epidemic encephalitis, *i. e.*, the subacute and chronic forms.

Modes of Onset.—In a small percentage of cases the parkinsonian state is recognized immediately or shortly after the patient's recovery from the acute attack of epidemic encephalitis. It is usually an incomplete picture of the typical syndrome consisting of a change in the individual's facial expression variously described as fixed, blank, stary, or expressionless; the motor activities are generally slower than the patient's former normal behavior particularly in the field of the automatic associated movements such as the swinging of the arms in walking, the manner in which he sits down on and arises from a chair. These individuals are often unaware of the change in their appearance and motor behavior patterns, but friends and relatives immediately recognize the change and correctly describe it as being "a general slowing up." There are those who are keenly aware of the change themselves and note that they do not blink so often as they formerly did, that their arms do not move from the sides when walking and speak of feeling stiff, awkward and incapable of responding quickly in a motor sense. This general hypokinetic state may be associated with a feeling of fatigue, weakness or tiredness and the patient may attribute slowness of action to the latter with the reassuring thought that it is only a part of the temporary convalescent period. To this clinical picture may be added hypersomnolence with or without nocturnal insomnia, or intractable insomnia without the slightest suggestion of diurnal somnolence. The hypokinetic state of the lingual and throat muscles, insufficient to produce conscious dysphagia, accounts for the accumulation of saliva in the mouth with drooling when the patient bows his head or on the pillowcase at night.

One may expect to encounter the above picture in all degrees of progression yet without a suggestion of tremor in any part of the body. On the other hand, the first symptom of the parkinsonian state may be tremor without obvious slowness of voluntary motor activities or alteration in the automatic associated movements. On returning to his normal routine after recovering from the acute attack, the individual may notice the development of a fatigue tremor in one limb, upper or lower, soon becoming more persistent, more troublesome and eventually constant. The tremor in the hand, for instance, may appear when the limb rests in an awkward position or when using the member for fine manual acts such as writing and sewing. In the lower limb it may appear only when that leg is crossed over the other knee or when the foot is so placed on the floor as to put the tendo achillis on tension. Such an apparently minor symptom generally forebodes the appearance in months or several years of parkinsonism on that side of the body, even though the importance of the tremor in the early months is overshadowed by associated disturbances in the sleep rhythm, physical weakness, emotional instability, character changes and the like. Of particularly sinister omen during this period is a rapid loss of weight since it is frequently followed by the rapid development of the parkinsonian manifestations.

Given the above conditions, namely, an acute attack of epidemic encephalitis followed shortly by such symptoms, no diagnostic question can arise. It is quite a different situation in the absence of manifest evidence of the acute invasion of the central nervous system because many other pathological processes or constitutional disorders are capable of causing sleep disturbances, general weakness, neuroticism, slowness of psychomotor activity, tremor, etc. The clinical approach is also less certain in the given case, even with a more or less questionable history of acute encephalitis, when many years have elapsed between that attack and the appearance of recognizable parkinsonian symptoms and signs, a not infrequent experience. In the author's present series of cases there are

instances of comparative normalcy, physically and vocationally, over periods ranging from several years to thirteen years. After the process of identification and establishing the cause and effect relationship, a fine-tooth comb analysis of the interval period brings to light very interesting postencephalitic clinical material with the possibility of identifying not only incipient parkinsonian states but even preparkinsonian criteria.

Preparkinsonian Fragments.—1. *Abnormal Automatic Associated Movements.*—A significant preparkinsonian sign is the automatic flexion of one forearm in walking with a slow but steady ascent of the hand in front of the trunk, and not until the hand enters the lower limit of the patient's visual fields does he become aware of the fact. He will then consciously drop his hand but with a few more steps the hand again rises and remains poised in mid-air close to the trunk, much to the embarrassment of the individual. The involvement may be more limited in its segmentation when only the fifth finger becomes strongly abducted and rigidly extended. Other patients describe such an automatic movement occurring when engrossed in some such mental activity as reading; the individual suddenly finds himself distracted by an uncomfortable pressure in the lower abdomen caused by the hand slowly moving along his lap until the hand presses deeply into the abdominal wall. Or, the forefinger, of the hand resting on the paper while the individual writes, slowly rises in full extension without the person's knowledge until he starts a new line and then sees the extended forefinger. Occasionally both arms are involved and the hands slowly rise in front of the person until they reach the level of the chest. One young woman so affected attempted to overcome her embarrassment by raising her hands still higher intentionally as though she were adjusting her hat, and in this way she thought that passersby would not take especial notice of her raised hands.

2. *Hyperkinetic and Tonic Manifestations.*—Not infrequently the parkinsonian patient, in retrospect, will relate an early experience with his foot or hand which would either move slowly and rhythmically or go into a tonic spasm. For

instance, while sitting with knees crossed the foot of the crossed leg will start moving up and down in a rotary manner unbeknown to the patient until someone calls his attention to it. Another may find that the toes of one foot are continually pulling strongly up and down as his foot rests on the floor. Shifting of the feet alternately backward and forward sometimes is beyond the patient's control and he must get up from his seat lest he disturb others about him. The writing hand may grasp the pen so tightly as to make further writing impossible, and patients have referred to this as "grabbing the pen as though my life depended on it." It occurs with the steering wheel in hand and the individual is often embarrassed in traffic because of his inability to release his hold quickly enough to reach for the gear-shift handle; this symptom is nothing more than an example of perseveration. In the present series of cases there are three patients who had a slow rolling movement of the lower jaw for several years before the parkinsonian state was recognized. One woman came to look upon this symptom as a habit spasm and said that she had it for about ten years beginning shortly after her acute attack of sleeping sickness. A slow, rhythmical, ticlike movement of one corner of the mouth is reported by five patients in this group as having been the first indication of trouble.

3. *Oculogyric Crises and Blepharospasm*.—The diagnostic significance of tonic eye-rolling attacks is now unquestioned and one should not hesitate to identify such a symptom as encephalitic even in the face of negative past and present evidence. The attacks come on without warning, save in the minority where there is an aura of one form or another, and the patient suddenly finds himself unable to look straight ahead or continue reading because he cannot get his eyes down to the normal position. The oculogyration is generally upward and to one side, less frequently laterally deviated or downward. In the great majority of cases the attacks are tonic and remain deviated for minutes to hours. (A very rare form of attack is clonic spasm with the eyeballs moving sharply up and down.) The victim is unable to force the eyeballs down

and in desperation buries his head in a pillow and remains in bed until the attack subsides. Others can overcome the tonic spasm temporarily but only with great effort and then there is an associated clonic blepharospasm which ceases only when the eyeballs turn upward again. Great mental distress is experienced during the attack as well as numerous somatic dysesthesias and discomforts, particularly dizziness. Five patients of this group have committed suicide during an attack.

4. *Disorders of the Respiratory Mechanism.*—Hyperpnea in attacks occupies nearly the same position in the diagnostic scheme as the oculogyric crises. Should any physician observe a young, healthy-looking individual go through the characteristic cycle of a Cheyne-Stokes respiratory attack his first thought should be of the probable encephalitic background. These attacks recur at irregular intervals, and at the point of apnea the patient may lose consciousness momentarily and fall to the floor, or the facies become fixed as though the patient were having an attack of petit mal. Other respiratory attacks take the form of rapid breathing (hyperpnea) or very slow breathing (bradypnea). In other cases the respiratory rhythm may be very irregular and not follow any fixed rate or arrhythmia. Various bizarre movements of the trunk and upper extremities are utilized during the attacks in an attempt to overcome the discomfort by throwing into action the accessory muscles of respiration. Frequent sighing respirations may constitute the only respiratory disturbance or one may encounter various nasopharyngeal and palatal tics very much like habit spasm with sniffing, snorting, clearing the nose and throat or making laryngeal sounds from simple clearing of the throat to continuous moaning. Paroxysms of coughing occasionally disturb the encephalitic as well as changes in the quality of the voice such as suddenly breaking or an elevation in the tone with gradual weakening of the sound until the patient is unable to talk. These manifestations are also episodic and have their component of psychical overreaction.

5. *Postencephalitic Dyspituuitarism.*—Between the acute attack of encephalitis and the later developing parkinsonian

state there occasionally occur disturbances in menstruation, fat metabolism and ectodermal alterations. Amenorrhea is quite a common aftermath and may persist for many months or years. It is associated with obesity and a rapid gain in weight of 50 or 60 pounds within a year. Hirsutism has been observed occasionally in these individuals with a change in the texture of the skin and the appearance of seborrhea facialis. The latter has been repeatedly pointed out as being a very common postencephalitic manifestation. Polyuria and polydipsia may be associated with the foregoing manifestations but are just as often present independent of them constituting the symptom-complex of diabetes insipidus. The pituitary gland is not the offending structure, the source is to be found in the neural connections of the pituitary in the interbrain. The central localization for these dysfunctions is further substantiated by the not infrequent finding of pupillary anomalies in these obese amenorrheic women, changes ranging from pupillary inequality and sluggishness of reaction to light to typical Argyll Robertson pupils.

6. *Miscellaneous.*—The preparkinsonian state is often unfathomable because of the vagueness of the subjective distress and the nonspecificity of the symptoms. But it is well to keep in mind the possible masked encephalitic background and search carefully for early signs of incipient parkinsonism the like of which will be described later. Chronic tiredness, loss of initiative, slight depression of mood, broken sleep, nervousness and shakiness of the hands when working under extra pressure and when excited, hypochondriacal tendencies, diurnal drowsiness, persistent aching in one limb, dizziness, loss of weight, a subjective sense or awareness of slowing of the thought processes are symptoms described by many chronic encephalitics before signs of parkinsonism become evident. Little wonder that these patients are subjected to thorough medical and surgical investigations and treatments for the purpose of removing all sources of infection purely on an empirical basis. Not uncommonly do we hear that one or another parkinsonian symptom or sign came on shortly after a minor surgical pro-

cedure such as tonsillectomy or the extraction of several teeth. Personality and character changes, especially frequent in children following acute epidemic encephalitis, may present a diagnostic problem in adult life and the nature of the change is recognized only in the light of a history of an acute attack of encephalitis or in the presence of parkinsonian evidence. Finally, it may be well to call attention to an interesting sign in young adults in the form of involuntary opening of the mouth which the patient can overcome but only momentarily. It is often present with the full-blown picture of paralysis agitans (encephalitic) but occasionally is an early sign long before the parkinsonian picture becomes typical.

Objective Diagnostics.—For absolute identification of any or all of the above described clinical material it is essential to recognize one or more early parkinsonian physical signs by a careful scrutiny of the appearance of the individual for changes in the facies, posture, attitudes, automatic associated movements, muscle tone as well as hyperkinetic unrest and evidence of neurovegetative dystonia. The facial changes include a seldom changing expression often referred to as fixed or blank, paucity of facial movements in talking and in emotional expression, a lessened frequency of the blink, and hypoactivity of one corner of the mouth in talking which may not be present when the patient voluntarily retracts the corners of the mouth (this may be reversed, *i. e.*, greater innervation in smiling than in voluntarily retracting the corners of the mouth, the so-called "dissociation of volitional and mimic innervation"). The posture and attitudes are characteristic and refer to any unusual manner, generally awkward, in which the patient holds his head, trunk and upper extremities. The elbows are more flexed than normal and the hands are held more to the front of the thighs than to their sides. The relative position of the fingers and thumb to one another as well as in relation to the palm is a very important feature of the early diagnostic criteria and will be discussed in a separate paragraph. The automatic associated movements are deficient in that the arms do not swing in association with the contralateral

lower limb when walking, the general motor behavior of the individual is slow and awkward not only in walking but in sitting down and arising from a chair. Frequently a limb remains poised in an awkward position either resting on a fixed object or just above the same. In turning toward the direction of a sudden auditory or visual stimulus the patient will turn his eyes more quickly than he will his head which is another evidence of dissociation in the automatic associated movements. This analysis of the motor functions, voluntary and automatic, can be carried on to apply to every act the human being is capable of performing.

A very helpful sign is the cogwheel motor phenomenon more often elicited in the biceps muscle. The examiner grasps the patient's arm in such a manner as to palpate lightly the belly of the biceps muscle while with the other hand the patient's forearm is alternately flexed and extended with variable speed at which time an irregular or broken relaxation of the biceps muscle is felt, a sensation akin to a cogged wheel rumbling over a plane surface. At the same time one will observe that the biceps muscle is overtoned as compared to the normal, hence the term "cogwheel motor rigidity." The phenomenon may be elicited in other muscles, particularly the triceps and forearm muscles, the latter by alternately flexing and extending the wrist. This is a sign of extrapyramidal disease of which paralysis agitans is an example. By hyperkinetic unrest is meant the presence of tremors of any kind and in any part of the body ranging from extremely localized fascicular or fibrillary tremors to coarse jactitations of an entire extremity. One should not expect to meet only with the so-called "typical pill-rolling tremor" in the encephalitic form of parkinsonism, because it is not the rule although it occasionally occurs. In the early stages the tremor may not be constant and be observed only when the patient holds his hands extended in front. A tremor may not be present when the limbs are at rest but brought out only with action, the intention tremor. It is quite characteristic, however, for the paralysis agitans tremor to continue with the limb at rest and cease entirely during the

performance of an intended act. In this portion of the survey we also include fluttering of the eyelids, localized tics, particularly slow, rhythmical twitching movements as of the neck with low amplitude of excursion indicating an incipient torticollis. Contrary to the characteristic loss of swinging movements of the arms in walking, occasionally one may observe an overactive and bizarre associated movement of one arm while the patient walks. Other involuntary movements occur very early in some instances such as tasting movements of the lips even with smacking sounds, movements of chewing, overaction of the tongue while talking so as to produce lisping or even mutilated articulation by the tongue constantly "trying to get out" through the oral orifice. The author has reported a very unique manifestation in the form of a rhythmical ticlike upward movement of the auricle due to involvement of an extra-aural muscle, and another case with a rotary movement of the auricle from involvement of the intrinsic muscles of the ear. Were it not for the presence of certain tonal signs in the hands the encephalitic nature of the tic would not have been considered. Quite a number of other kinetic manifestations may be observed which have more or less diagnostic significance to the individual clinician according to his personal experiences.

The term "neurovegetative dystonia" is used to include symptoms and signs referable to the autonomic nervous system such as the degree of pupillary dilatation or contraction, hypersalivation, bradycardia, tachycardia, motor and secretory dysfunction of the gastro-intestinal tract as indicated by the symptomatic expression and confirmed by roentgenological evidence; the dysfunction includes hypo- and hypersecretion and the same with motor innervation, the colon being affected either with a state of spastic colitis through all degrees of motor dysfunction up to an occasional instance of megalocolon, there being a number of reported cases in the literature of post-encephalitic Hirschsprung's disease. The examination should not fail to include the convergence power of the eyes because the most commonly observed postencephalitic ocular residuum is loss of ocular convergence.

Diagnostic Triad for the Early Recognition of Incipient Parkinsonism.—The author's triad (Arch. Neurol. and Psychiat., vol. 22, p. 709, 1929) is based upon the finding of asymmetry in the posture of the hands, in the manner of spacing the extended fingers and in the manner of performing rapidly repeated movements of touching forefinger to thumb. In the first sign one will note an increased flexion of the interphalangeal joints of one hand so that the thumb and forefinger are brought into apposition while in the opposite hand the fingers and thumb have a normal appearance of relaxation when the hands hang by the sides. The change may also consist of hyperflexion at the metacarpophalangeal joints with extension at the interphalangeal joints which still brings the thumb and forefinger together. For the second test the patient extends his upper extremities forward with the fingers separated and it is observed that on the affected side the thumb is not abducted as much as in the less involved extremity and the other fingers are irregularly spaced or closer together than in the opposite hand. During this test one will observe that there is a tendency for the extended position of the fingers to become exhausted with a gradual sinking of the fingertips to a lower level, and this might also apply to the wrist. The elbow of that limb will be seen to be less fully extended and even the hand incompletely pronated as compared to the other limb. In the third test the patient has his closed hands before his face and then attempts to rapidly and repeatedly bring the tips of his forefinger and thumb together when it will be seen that in the affected limb the height of the excursion is less than in the other hand, that the movement is less eumetric and is liable to become exhausted until it gradually stops while the other hand continues the normal movements. These signs merely indicate the existence of an early increase of muscle tone in the one limb. Although the triad may be positive in both limbs, it is true that the disease will manifest itself in its earliest stage by a greater development on one side than the other. This triad has been frequently elicited in persons who have not the slightest appearance of a parkinsonian on cursory

inspection. A positive triad may exist before the affected limb stops swinging in association with the contralateral lower limb in walking. An unequivocal incipient parkinsonian complex is constituted by the grouping of a positive unilateral triad with a suggestion of the cogwheel motor phenomenon in the arm, a suggestion of hypoactivity of the corner of the mouth on the same side either for emotional or voluntary innervation, and paralysis of convergence. This combination of physical signs has often been recognized in persons unsuspected of having parkinsonism, and on the strength of these findings the future disability of the patient was predicated only too truly because of the present impotence of our therapeutic armamentarium.

Treatment.—It is only fair to say at the start that there is no specific therapy for chronic epidemic encephalitis including parkinsonism. The virus causing acute epidemic encephalitis has not as yet been identified and no vaccine or serum has been produced which will effectively give or induce passive or active immunity. The consideration of immunological principles may not be as applicable to the chronic forms of the disease as to the acute because in our present state of knowledge it has not been definitely established that the parkinsonian harbors the active virus as does the acute encephalitic patient. Even the future discovery of a specific viricidal substance may not cure parkinsonism in the advanced stages because the degenerated brain tissue could not regenerate. Hope would be held out for those in the early stages of the disease and for this reason it behooves physicians to recognize the clinical manifestations in their incipient forms.

Nonspecific immunological attacks have been made on the disease with very little success, the methods ranging from intramuscular injections of milk to artificial hyperpyrexia through the use of physical or biological measures including malarial therapy. In the author's experience the strenuous fever therapy has done more harm than good to the parkinsonian. It would serve no purpose to enumerate the great number of foreign protein substances used because of the uniform lack of success in the therapeutic results. Many chem-

icals have been used intravenously but without convincing results. Von Economo, "father" of the disease, insisted in his late monograph on the use of iodine intravenously in heroic doses, 100 cc. of Pregl's iodine intravenously daily. In addition to iodine therapy he produced artificial fever with the injection of a material he called vaccineurin, a nonspecific protein. Von Economo introduced this treatment for the acute disease but suggested that all patients in the chronic stages be given the same treatment providing he had not received it previously during the acute attack. No such enthusiasm is expressed in this country over this treatment for obvious reasons.

The treatment of parkinsonism thus becomes limited to palliation of symptoms which is, fortunately, fairly satisfactorily accomplished by physiotherapy and certain medicaments. Knowing that parkinsonism is an incurable disorder and that the patient at best can expect only a stay in the progress of the disease, no effort should be spared, all conditions being equal, in instituting a strict hygienic regime for the purpose of conserving mental and physical energy. The parkinsonian has reached a point in life where he must balance his mental and physical budget if he would have the best of his remaining years. This applies to regularity in habits and moderation in all activities, physical, emotional and intellectual. The daily warm bath for thirty minutes followed by ten minutes of underwater passive and active exercise of his extremities is the most valuable form of physiotherapy. General massage does much for the physical comfort of the patient and his sense of well-being, but it must be given regularly and by a conscientious operator who is capable of differentiating between medical massage and a rubdown. A difficult but essential part of the program is reeducational postural and associated motor training which utilizes conscious direction of these motor behavior patterns in lieu of the lost automatic control. There are a number of these motor reeducational exercises and it is beyond the scope of this paper to elaborate thereon.

Greatest reliability is placed on derivatives of the solan-

aceous group, namely, hyoscine (scopolamine), atropine, and stramonium. Their effect is to depress the excitability of the parasympathetic nervous system with resultant lowering of the muscle tone which gives the patient a relaxed feeling and a sense of motor freedom. It is well to alternate these drugs so that the patient does not develop too great a tolerance to any particular one. Hyoscine hydrobromide is given in $\frac{1}{2}$ grain doses three times a day at the beginning with gradual increase up to $\frac{1}{2}$ grain according to the individual patient's tolerance. Where there is much tremor or other forms of nervous unrest it is of advantage to combine the hyoscine with phenobarbital, $\frac{1}{2}$ or $\frac{3}{4}$ grain three times a day. When no further improvement takes place or when hyoscine fails "to hold" the patient, stramonium may then be more effectual. The latter is used in the form of fresh tincture or a soft pill made from the fresh leaves, or the extract of stramonium in doses equivalent to 25 minims of the fresh tincture to start with and gradually increasing the dosage up to the equivalent of 90 minims per dose three times a day. Atropine sulphate is exhibited in a dilution wherein 1 minim contains $\frac{1}{1000}$ grain. In this manner the dosage can be increased by 1 drop and gradually worked up with the increasing tolerance of the individual until he receives even as much as $\frac{1}{10}$ grain in occasional cases. No two parkinsonians will react similarly to the various drugs, and it cannot be said that one or the other of this group is more beneficial for tremor or hypertonicity than the other, it is merely a matter of the personal equation. The remainder of the drug therapy resolves itself around symptomatic prescribing for the relief of the many and varied complaints of subjective distress.

Tantamount to most of the treatment of parkinsonism is psychotherapy which is to be used in conjunction with everything available be it physiotherapy, artificial fever or drug therapy. These patients are highly suggestible, tend to become hypochondriacal through morbid introspection, they are frequently depressed and develop persecutory trends and a number terminate their suffering by their own hand. A cure

should never be promised a parkinsonian but hope should not be destroyed. A generally acceptable dictum is—"Although cure cannot be promised, you may expect and hope for an arrest in the progress of your disease after which time we will see what can be done by reeducation."

CLINIC OF DRS. DONALD M. PILLSBURY AND
GEORGE H. FONDÉ*

UNIVERSITY OF PENNSYLVANIA

THE TREATMENT OF HERPES ZOSTER

IN common with other virus diseases, a specific treatment for herpes zoster is not available and one is forced to choose from a rather wide variety of therapeutic measures, many of them commended on the basis of experience with a few cases, few of them compared as to effectiveness with the results in control series, and none of them always successful. It seems timely, therefore, to consider the various methods of treatment suggested and to attempt a critical evaluation of each in an effort to outline a régime based on the best available information.

A short résumé of the principal features and variations in the course of herpes zoster will, we believe, emphasize the difficulty of an adequate analysis of the effectiveness of treatment. We may define zoster as a disease usually due to an unknown virus, occurring *sui generis* or during the course of a wide variety of other diseases, in which there are seen on the skin tense grouped vesicles on a highly inflammatory base, in the area innervated by one or more spinal ganglia or the homologous ganglia of the head, usually on the same side of the body. The vesicles may vary somewhat in size and the degree of inflammation may diverge widely, from a moderate erythema persisting for but a few days, to a destructive local gangrene. The more severe local reactions are noted particularly

* From the Department of Dermatology and Syphilology, University of Pennsylvania, and the Skin Clinic of the Children's Hospital, John H. Stokes, M. D., Director.

in aged debilitated individuals, and the prognosis in this regard must be guarded in such patients. An adenopathy of the adjacent lymph nodes is almost invariably found and this has been emphasized as a differential criterion from herpes simplex.

In a discussion of the treatment of zoster one must be mindful of the wide variation in the sequelae, dependent in part upon the structures innervated by the affected ganglia, and of the unpredictable, almost quixotic nature of the subjective symptoms noted. The pain and discomfort are often not at all proportional to the severity of the local manifestations. The following are the special regional forms of zoster most frequently offering difficulty in diagnosis and sometimes productive of unusual and severe sequelae.

Zoster Ophthalmicus.—In this type there is noted first an edema and swelling of the lids, with conjunctivitis and keratitis. Headache is common, and pain is more frequently encountered and often more severe than in thoracolumbar zoster. Aside from the immediate local changes in the eye (consisting of disturbances in the lacrimal secretion, appearance of vesicles on the cornea, and interstitial keratitis with or without ulcers), iritis may develop, and subsequent glaucoma has been described. Disturbances of the ocular innervation, which may sometimes be permanent, are seen in about 12 per cent of the cases.¹ Typical herpetic lesions are usually seen elsewhere in the region and the diagnosis must ordinarily rest on this finding.

Zoster Oticus.—The most significant contribution to a clarification of this at times puzzling syndrome was made a quarter century ago by Hunt.² He divided zoster about the ear into several types, in one of which the geniculate ganglion alone is involved, and the others in which mixed involvement of the facial, the acoustic, the auricular branch of the vagus, and the second and third cervical nerves occurs. Hayman³ states that zoster oticus constitutes 28 per cent of all zoster about the head. We have recently observed a patient which illustrates the difficulty of early diagnosis in such cases. A woman, forty-five years old, had had a dermatitis of the left

external auditory canal for years. When first seen in the otolaryngology department of the University Hospital, she presented an erythematous swelling of the ear and preauricular region. She complained of headache (an almost constant finding in cephalic zoster) and some pain in the affected area. The morphologic appearance suggested erysipelas strongly but there was no fever. The left anterior cervical lymph nodes were enlarged. A provisional diagnosis of cellulitis was made, but with the appearance of the typical vesicles of herpes in the region anterior to the ear the true nature of the process became apparent. There had been no extension of the erythematous area and the vesicles, not discernible early in the process, became increasingly evident as the erythema subsided. There was no neuralgia, pain being frequently absent in herpes oticus, and under treatment with x-ray, salicylates, autohemotherapy, and calamine lotion, an excellent end-result was obtained.

Confusion of herpes zoster and simplex may occur, particularly when herpes simplex appears at unusual sites or is more extensive than that ordinarily seen. The rarity of recurrence in zoster and its frequency in simplex are, of course, well known. The most frequently encountered "unusual" sites of herpes simplex are the buttocks, particularly in women, and the genitalia in men. In many cases the differentiation of zoster from simplex cannot be made without resort to animal transfers in which, on scarification of the cornea of a rabbit with the contents of a herpes vesicle, a typical keratitis develops if the case is one of herpes simplex, while in zoster this reaction is not noted. Auto-inoculation is possible in herpes simplex.⁴ In this connection the possible development of recurrent herpes simplex at the sites of inoculation must be kept in mind, especially since repeated inoculation has been suggested as a means of treatment.

Before proceeding to a discussion of the individual methods of treatment of herpes zoster we wish to emphasize several features of the course of the disease which have proved a source of difficulty in the interpretation of the specific effects of the various treatments in our series of 120 cases, and which

are, we believe, in part the reason for divergent opinions concerning the effects of treatment and for the frequently undue enthusiasm with which new types of therapy are introduced. The initial symptoms and sequelae of herpes zoster are in general directly proportional to the age of the patient. We have never seen a case of severe postherpetic neuralgia in a child under twelve in a fairly large clinical material at the Children's Hospital, and this impression of the relatively benign course of herpes in children is confirmed in the literature. On the contrary, zoster of relatively restricted extent in older individuals may be followed by neuralgia of a most persistent and exhausting character for months and even years after the attack. In young adults one often sees zoster of wide extent in which there is little complaint of pain and no interference with the patient's activities. In a case of bilateral herpes zoster observed by one of us (D. M. P.) in a man of thirty-seven, the patient stated that his subjective symptoms had consisted only of slight burning and tingling in the skin before and for two days after the appearance of the lesions. Obviously the results of any type of treatment in this case would have been rated as excellent as far as the neuralgic pain was concerned, whereas he had had no treatment.

It is apparent, therefore, that the probable symptomatic course in an individual case is often unpredictable except in children, and that only in relatively large series of cases including similar age groups, and with adequate control cases, can an accurate evaluation of therapy be made. The literature concerning the therapy of herpes zoster is in general distinguished by an absence of controls.

We shall consider in particular those measures with which we have had personal experience or concerning which a fairly adequate amount of data is available in the literature. These include (1) local measures, (2) drugs by mouth, (3) x-ray, (4) autohemotherapy, (5) pituitrin, (6) intravenous sodium iodide, (7) physiotherapy.

Local Treatment.—There seems to be no doubt that a cardinal principle in the treatment of zoster is to keep the

lesions dry. While there is ordinarily surprisingly little tendency to secondary infection, the opportunity for this is increased if wet dressing or poultices are employed. A simple calamine lotion is effective in most cases. The particular formula which we employ is as follows:

Calamine	
Zinc oxide	4
Phenol	
Glycerin	1
Rose water	
Lime water	âã q.s. ad 120

In any but cases with superficial and relatively nondestructive lesions we believe it is preferable to omit the phenol, in spite of its local anesthetic effect. One half of 1 per cent each of menthol and camphor are a good substitute, except about the eye, where their use may produce marked lacrimation.

At times, particularly when there are lesions in intertriginous regions, a dusting powder may be useful. The following is suggested:

Camphor (pulv.)	0.6
Zinc oxide	
Boric acid (pulv.)	3.0
Talc	50.0

Local anesthetics are generally rather disappointing in their effect and have the disadvantage of retarding healing if any marked ulceration has occurred. If one is desired, anesthetic is useful, and may be incorporated in the above dusting powder in a strength of 1 to 5 per cent or in equal parts of lanolin and petrolatum. Nupercaine ointment (1 per cent) has seemed quite effective in some cases, and should be applied in small amounts thoroughly rubbed into the skin.

Occasionally the lesions become markedly pustular, and true secondary infection may also occur. Freshly prepared 1:4000 solution of potassium permanganate compresses, applied one-half hour three times a day, are useful. This may be followed by the application of a 2 per cent solution of gentian violet, or an ointment containing equal parts of the official ammoniated mercury, boric acid, and zinc oxide oint-

ments. The ointment should not be applied thickly, since this has the effect of allowing undue accumulation of exudate, and in some cases seems to retard healing.

Fox⁶ has reported a method of applying an occlusive dressing with paraffin, in which he noted good symptomatic relief during the eruptive stage. A paraffin having a melting point of 114° to 117° F. was sprayed on the affected skin and covered with cotton held in place by bandaging. Fox recommends applying the paraffin daily, with careful gentle removal of paraffin remaining from previous applications. He noted no effect on postherpetic neuralgia.

Therapy by Mouth.—It is our custom to prescribe salicylates unless the process is very limited in extent or symptomless. Ten grains of sodium salicylate three or four times daily in adults has been the dosage employed. The barbiturates are useful for sedative and analgesic effect. We have discontinued the use of compounds containing amidopyrine. We have the feeling that morphine and its derivatives are employed much more extensively than is necessary, and the danger of inducing morphine habituation in prolonged postherpetic neuralgia must be considered.

In cases with ophthalmic involvement, consultation is advised. Fry⁶ suggests the instillation of a 1 per cent atropine solution routinely three or four times daily, the use of 1 per cent holocaine solution if pain is present, and bandaging of the eyes if corneal ulceration occurs.

x-Ray.—This method of treatment has in our experience at times been quite striking in its effect on the local lesions but has frequently been disappointing in abating the neuralgic pain. Among the first to report an extensive experience with the method was Vignal⁷ who believed that its value lay in the specific effect on the resorption of a round cell infiltrate of the spinal ganglia and posterior spinal roots. He stated that the pain may be increased after the first or second treatment but that improvement is ordinarily noted after the third irradiation. He recommends the employment of diathermy along with the x-ray.

The largest series of cases treated by this method which has come to our attention has been reported by Keichline.⁸ He irradiated both the affected skin and the corresponding spinal ganglion in 62 cases. The factors which he employed were as follows: 148 r, 3 mm. Al, 30 cm. distance (K.V. not given). He found that in 90 per cent of his cases only one dose was required, while 8 per cent were given a similar dose the following day. In 2 per cent of his cases three doses, given at ten-day intervals, were required.

Pendergrass⁹ has kindly given us his opinion of the value of and his method of administering x-ray in these cases. He has noted a variable effect, "some cases responding well while others do not." When the eruption is present he has employed the following factors: 135 K.V., 1 mm. Al, 30 cm. distance, 150 r, repeating this dose daily for a maximum of four times. For treatment of the ganglia and roots after the eruptive stage he has used the following: 200 K.V., 50 cm. distance, 0.5 mm. Cu, 50 to 200 r daily, for four or five applications.

We have treated 50 of our cases of herpes zoster by x-ray. We employed it particularly in cases showing severe local lesions or having appreciable neuralgic pain. The factors employed were 100 K.V., 30 cm. distance, no filter, 65 r daily to every third day for four or five doses. We have been impressed with the effectiveness of this measure in reducing the inflammatory reaction at the site of the lesions but have noted no very striking response of the pain. It is probable, of course, that very little effect on the spinal ganglia could be expected with this type of superficial therapy.

Autohemotherapy.—This method of treatment is widely employed in a variety of dermatologic conditions, of which zoster is one. Its use in general is almost entirely empiric and the theories concerning its mode of action are exceedingly tenuous and lacking in proof. We have employed it in 30 cases, frequently in conjunction with x-ray therapy. In one case there was a striking response which seemed definitely attributable to this factor in the treatment. The method was favorably reported on by several observers at the Nancy

meeting of French dermatologists in 1923,¹⁰ and Beeson¹¹ has reported a series of 7 cases treated solely by this means. None of his cases had postherpetic neuralgia and the response of the local lesions was good.

Aside from its theoretical action, probably in effect similar to that of a foreign protein, it cannot be denied that autohemotherapy has a psychic value, especially when the procedure is performed in a not too casual manner. In view of the increasing importance of the psyche in many dermatologic conditions, including warts, the possible value of such an effect should not be lost sight of. Autohemotherapy is an almost completely innocuous procedure, when properly performed, and while its value in herpes zoster can hardly have been said to have been demonstrated adequately, further study of it seems worthwhile and its retention as a harmless ritualistic procedure seems defensible.

Pituitrin.—Following the introduction of this method of treatment in America by Sidlick,¹² in whose report is quoted the European experience of Vandel,¹³ several other well considered and extensive reports concerning it have appeared. In four of Sidlick's cases the relief from pain was so prompt following the injection of pituitrin as to hardly admit of any objection to the argument that this treatment was the causative factor. Niles¹⁴ reports 16 cases treated with pituitrin, in which 11 were well in an average of eight and one-half days. Niles included a control series treated in other ways, in which the results seemed less satisfactory in the cases in which the end-result was known. He saw no difference in the effect of surgical and obstetrical pituitrin.

Somers and Pouppirt¹⁵ report their experience with pituitrin in 22 cases and offer an interesting theoretical consideration of its action. They make a distinction between two types of pain noted in zoster, the first type being of a sharp, stabbing, shooting character and of unlocalized distribution, the second being localized and of a burning, itching, shooting nature. They state that cases having the first type of pain most frequently suffer from prolonged neuralgia. The pain in

all their cases was of the second type and was relieved within six hours by pituitrin. They believe that the pain of zoster is the result of irritation of the sensory nerve endings by local vasodilatation and that the use of a vasoconstrictor such as pituitrin is reasonable on this basis. We have employed the extract in 7 cases and in at least 2 of these the relief from pain within a few hours after injection was striking.

Sidlick administered obstetrical pituitrin intramuscularly in doses varying from 0.5 to 1 cc. Somers and Pouppirt gave surgical pituitrin subcutaneously, starting with a dose of 0.2 cc. and increasing by 0.1 cc. increments up to 1 cc., at intervals of one to two hours. The larger doses were given only to young adults.

It is obvious that certain definite precautions must be observed in the administration of the extract. Pregnancy is, of course, an absolute contraindication, though Somers and Pouppirt state that pitressin may be used. In any occlusive vascular disease, particularly when the coronary arteries are involved, and in hypertension, we do not believe its use justifiable. Increased intracranial pressure is a contraindication. Patients must be warned of the probable effect of markedly increased peristalsis and the use of the extract in patients with any severe grade of constipation must, we believe, be guarded. Sidlick noted faintness in some of his cases.

From our own and the reported experience of others, we believe pituitrin is of definite value in many cases. One of its advantages is that the probable effectiveness of the method in an individual case can usually be determined within three or four days.

Sodium Iodide.—Ruggles¹⁰ has reported 15 cases of zoster treated with gratifying results by intravenous sodium iodide. His method consisted in the administration of 20 cc. of a 10 per cent solution on the first, second, fourth and seventh days. We have used this treatment in 15 cases, in all but 2 of which either autohemotherapy or x-ray were also used. In one case treated with sodium iodide alone the local response was prompt. The patient was a boy of nine in whom the eruption was orig-

the concomitant administration of 10 cc. of the patient's own whole blood intramuscularly is suggested.

3. If pituitrin is contraindicated or ineffective the administration of 10 cc. of a sterile 10 per cent solution of sodium iodide on successive days is suggested, preferably combined with

4. x-Ray therapy: (a) 75 to 150 r, 100 to 135 K.V., 30 cm. distance, without filter or with 1 to 3 mm. Al every one to three days to the skin lesions; (b) 50 to 200 r, 200 K.V., 50 cm. distance, 0.5 mm. Cu filter daily for four or five days over the affected ganglia.

5. General ultraviolet light in suberythema doses, protecting the areas exposed to x-ray, or better, natural sunlight, or dry heat.

6. Diathermy over the region of the affected ganglia.

7. Neoarsphenamine in tonic doses (0.3 to 0.45 Gm.) at four-day intervals for four doses, being certain that the patient does not have obvious organic syphilis and observing the rule of taking a "baseline" Wassermann.

CLINIC OF DR. THOMAS FITZ-HUGH, JR.

UNIVERSITY OF PENNSYLVANIA

GENETIC ASPECTS OF CERTAIN BLOOD-SYSTEM DISORDERS

DESPITE the danger to the student of hematology of listening too sympathetically to the siren song of "constitution pathology" with its seemingly easy answer to some unsolved problems of etiology, and despite the great complexities of genetic science (even as applied to *Drosophila*, not to mention *homo sapiens*) it seems nonetheless worth while to review the now accumulated data of clinical hematology from a genetic standpoint—with due apologies for the presumption.

The following list (Table 1) of anomalies and diseases of hematologic interest begins with hemophilia which has been called "the most hereditary of all hereditary disorders" and

TABLE I

- I. Blood-system disorders known to have a genetic basis.
 1. Hemophilia.¹ 2. Hereditary hemorrhagic telangiectasis.² 3. Hereditary hemorrhagic thrombasthenia.³ 4. Hemolytic ictero-anemia.⁴
 5. Sickle-cell trait.⁵ 6. Ovalocytosis.⁶ 7. Pelger's familial anomaly of nuclei.⁷
- II. Blood-system disorders believed by some authorities to have a genetic basis.
 1. Pernicious anemia.⁸ 2. Idiopathic hypochromic anemia and chlorosis.⁹
 3. Erythroblastosis of infancy.¹⁰ 4. Familial polycythemia.¹¹ 5. Gaucher's¹² and Niemann-Pick's¹³ diseases.
- III. Blood-system disorders which may possibly have a genetic basis.

<ol style="list-style-type: none"> 1. The leukoses¹⁴ 2. Lymphosarcoma¹⁵ 3. Leukosarcoma¹⁶ 4. Hodgkin's disease¹⁷ 	}	Malignancy?	<ol style="list-style-type: none"> 5. Purpura hemorrhagica¹⁸ 6. Agranulocytic angina¹⁹ 7. Favism²⁰ 8. Familial eosinophilia²¹ 	}	Allergic constitution?

ends with certain questionably classified entities whose chief claim to genetic consideration rests largely upon that uncertain hypothesis called the "allergic constitution"—which is probably partly genetic and partly the result of acquired intra-uterine transfer of sensitization.

Before entering upon a discussion of these conditions I would like to remind you of a few clinically important findings and deductions of genetic science. I am indebted chiefly to

Fig. 8.

Professor Mohr's admirable book²⁰, for the next two diagrams and their explanation.

In Fig. 8 I have attempted (after Mohr) to illustrate the simplest type of dominant and recessive unit character transmission employing respectively the conventional black and white rabbit symbols. If one wishes to work out the genetic possibilities of a certain dominant anomaly he may imagine that the black rabbit is the "anomalous" or "diseased" individual

and the white rabbit the "normal." If on the other hand a recessive anomaly is being considered the white rabbit becomes the diseased representative in a "normally" black population.

Since most human dominant anomalies are present in heterozygous form—very rarely in homozygous or "double dose" composition—it is obvious that the usual rule of dominant character transmission is: 50 per cent "affected" and 50 per cent "normal" offspring. When we find in the hereditary incidence of a given human anomaly an approximation

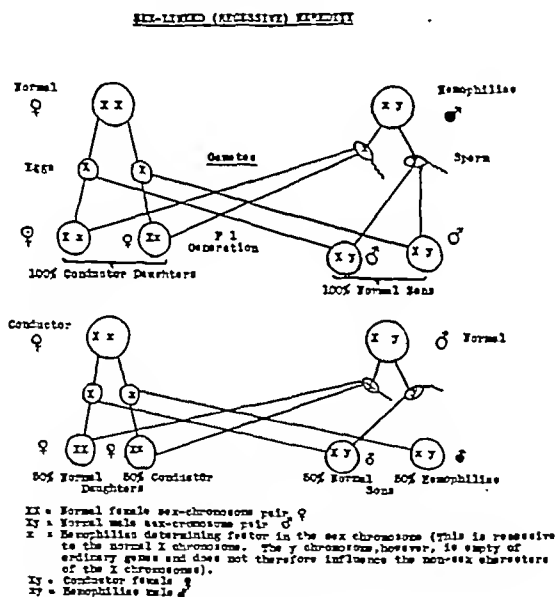

Fig. 9.

of this 50-50 ratio in each generation we are inclined to suspect a dominant gene factor. Despite the obvious logical fallacy of such a deduction, and despite the fact that there are other complex genetic modifications that may simulate this ratio it nonetheless appears to be a fairly sound inference if based on sufficiently accurate and numerous observations. On the other hand, dominant anomalies as observed in the clinic are rarely so striking and uniform as the "black rabbit symbol" would imply. There are modifying factors which may

make certain dominant anomalies mild and inconspicuous. Hence the apparent paradox that although dominant anomalies from a truly genetic standpoint do not skip generations (*i. e.*, exhibit no atavism) they nevertheless clinically sometimes appear to do so. This "paradox" is frequently encountered in the heredity of hemolytic ictero-anemia and hemorrhagic telangiectasia.

The genetics of hemophilia are illustrated (after Mohr) in Fig. 9. This is another type of mechanism—the so-called "sex-linked recessive pattern"—to which we shall refer again.

Some Blood-system Disorders Conditioned by Dominant Genetic Anomalies.—*Hemolytic ictero-anemia* of the Chauffard-Minkowski type is dependent in part at least upon the production of abnormally fragile and thick red cells²¹ ("spherocytes"). It is exhibited by both sexes, transmitted by both sexes, and varies in its manifestations all the way from a symptomless "latent" anomaly to a crippling and even fatal disease. A practically "normal" or latent "carrier" may transmit it in severe form to offspring—among whom it may also vary greatly in severity. This is merely one of the unsolved mysteries which include also the characteristic relapsing and remitting course of the disorder in any given individual. These facts point not only to complex genetic factors but also to the subtle interplay of environmental factors as well. Despite these mysteries this disease offers a most satisfactory therapeutic opportunity. The results of splenectomy are dramatic and gratifying—even though the underlying genetic "defect" of course remains.

In the two family charts presented in Fig. 10 the parent responsible in each instance for the disease in the children was unaware of any real ill health. In the H. family, however, the father was found to have an enlarged spleen, increased fragility of the red cells and a reticulocyte count of 10 to 15 per cent and in the M. family the mother had slight icterus and a moderately increased fragility. It might have been scientifically instructive (but probably humanly tragic) if "fate" had brought these two apparently normal individuals

together as husband and wife. Genetic science is replete with evidence that "a dominant gene, which when heterozygous causes only trifling malformations, may in double dose or homozygous condition cause very serious or even lethal disturbances." *

Hereditary hemorrhagic telangiectasia exhibits the same sort of hereditary incidence and the same inexplicable variability of manifestations as hemolytic ictero-anemia. Some years ago I called attention to the fact of apparent atavism²² in this—a genetically dominant disorder which strictly speaking cannot be truly atavistic. The practical importance of

HEMOLYTIC ICTERO-ANEMIA - A DOMINANT MENDELIAN TRAIT.

All individuals in this chart personally examined except case 2 who died of anemia and jaundice. Case 3 splenectomized with excellent result. Case 1 - mild - refused splenectomy.

All individuals examined. Case 1 "latent". Case 2 - age three years 8 months, case 3 - age eleven years and case 4 - age nine years all severe and all splenectomized with excellent results.

Fig. 10.

these "latent" or "mildly affected" carriers in the heredity of many dominant-gene anomalies cannot be overstated.

Ovalocytosis is, as far as is known, a harmless anomaly of human erythrocytes. It is I am sure more common than generally realized. My office technician has kept a record for the past few years of the occurrence in otherwise normal blood counts of patients showing 5 per cent or more of oval cells in the stained spreads. To be counted in these statistics the hemoglobin (Sahli scale) must be 80 per cent or better and the red cell count 4 million or better so as not to include "poikilocytosis." Our figures show a 6 per cent incidence of ovalocytosis in the last 600 normal-patient blood counts.

* Mohr: Heredity and Disease, Published by W. W. Norton and Co., Inc.

That this anomaly is probably a dominant one is suggested by the absence of atavism in well-studied families and by the nearly 50 per cent incidence in the generations exhibiting the trait. I have studied the reticulocytes, fragility, gastric acidity and agglutinins (blood type) of affected and nonaffected members of two families exhibiting this anomaly without discovering any significant correlations. Here too, however, it would be interesting to observe the effect of this "harmless" hetero-

1. Patient's maternal grandmother. 2. Patient's mother (who married twice). 3. Patient's half-sister. 4. Patient Mr. M.G., 5, 6, 7 siblings of the patient. 8. Nephew of patient. 9, 10, 11, 12 Children of the patient. 13. Grand-nephew of patient.

Fig. 11.

zygous dominant in double dose or homozygous composition. Such unions must occur if ovalocytosis is as common as I think

The *sickle-cell* trait is another dominant-gene anomaly which, like hemolytic ictero-anemia, may vary in different individuals from a harmless laboratory entity to a fatal disease. Unlike hemolytic ictero-anemia, however, there is no "cure" nor even a useful remedy.

Other Blood-system Disorders Known or Thought to be Genetically Conditioned.—*Hemophilia* is a disease of males only. Although absolutely hereditary it is constantly

cropping up, especially in the United States among the first or second generations of native-born boys descended from Old World grandmothers and great-grandmothers without a discoverable trace of the pathognomonic "family history." When one looks at the genetic mechanism (Figs. 9 and 12) it is easy to see how through several predominantly feminine generations (without perchance bleeder boys to keep the memory alive) conductor females might carry on a hemophiliac strain from mother to daughter with a good chance of losing track of the tell-tale record. We have had three boys recently in the wards of the University Hospital with classical hemophilia but with absolutely "negative" family histories. The diagnosis in each instance was established not only clinically (by the record of hemorrhages from trivial trauma since infancy, hemarthroses, etc.) and hematologically (by the prolonged coagulation time of the blood, with normal platelet count, etc.) but also by that pathognomonic test of platelet function²³ which I believe is conclusive. If hemophilic blood is collected carefully and allowed to "sediment," the platelets can be removed in the plasma from above the "buffy coat." Such hemophilic platelets (washed in saline) when added to freshly shed hemophilic blood do not hasten the coagulation of this blood. If normal washed platelets, however, collected from above the "buffy coat" of normal citrated human blood, are added in equal quantity to freshly shed hemophilic blood the latter clots quickly and normally. Hence if we have a known hemophiliac to furnish the "test-object blood," an undiagnosed suspect's blood platelets may be added. If the suspect's platelets cause prompt clotting of the known hemophiliac's blood then the suspect is not a hemophiliac. If the suspect's platelets, however, do not cause the hemophilic blood to clot any sooner than it is shown to do at the time spontaneously there is thus adduced strong evidence in favor of the diagnosis of hemophilia in the suspect.

Hemophilia has thus far resisted all efforts at curative therapy. The ovarian gland and estrus hormone therapy of Birch²⁴ has failed completely in our hands. The placental

extract therapy of McKhann²⁵ and his associates has also not been of significant value in the 3 cases in which we have tried it.

Space does not permit of detailed discussion of the other diseases and anomalies listed at the beginning of this review. I have attempted in the bibliography to include some important "leads" to their genetic consideration. Pernicious anemia and so-called "idiopathic hypochromic anemia" appear to have a common basis in gastric deficiency and occur often enough in successive generations of families to warrant the suspicion

Pedigree, showing sex-linked mode of inheritance in hemophilia. Squares indicate males; circles, females; black symbols, persons afflicted with hemophilia; circles with dots inside, conductor females; clear symbols with numeral inside indicate a corresponding number of unaffected offspring; means twins. Most of the hemophilic males died of hemorrhage at an early age. Note that transmission through the males in the second generation occurred. The male inherits hemophilia from his mother, however, never from his father.

Since conductor females cannot be differentiated from normals except by the test of reproduction it is obvious that in hemophilic families only the unaffected males can reproduce with impunity. (Adapted from Macklin (1)).

Fig. 12.

of a genetic predisposition. The pedigree (Fig. 13) taken from Heath's article²⁶ is a striking illustration of this point of view.

One must of course be critical of the assumption of a genetic factor if the assumption is made without due consideration of such factors as common family environment, contagion and common dietary deficiencies and excesses.

When one considers the malignancy-like members of the blood-system diseases from a genetic viewpoint there is very little convincing evidence to be seen. There are records, how-

ever, of familial leukemia, polycythemia, lymphosarcoma, etc. The analogies of human to mouse leukemia are striking; and the genetic factor may be championed just as well by those who believe in a virus cause as by those who adhere to the theories of a purely cellular mechanism of malignancy. For it has been shown that virus susceptibility has an important genetic basis.²⁷

Concerning the "allergic constitution" and blood-system disorders that may possibly be related thereto one may merely speculate.

DESCRIPTION OF CHART. - ● Died of anemia. ⊙ Living, has pernicious anemia. ⊕ Living, has secondary anemia.

Fig. 13.

I have a growing conviction that many puzzling "blood pictures" may eventually be shown to result from hematopoietic participation in the biologic reactions of idiosyncrasy and allergy. This suspicion includes some of the purpuras and other hemorrhagic states, leukopenias, hypoplastic and aplastic anemias, thrombocytopenias, and granulocytopenias. My present concept¹⁷ of the condition commonly called agranulocytic angina, which I have attempted to symbolize in Fig. 14, includes a complex liver-bone-marrow-blood-stream reaction on a sensitivity basis—which may or may not be genetically conditioned. Perhaps this is carrying the genetic viewpoint to a

THE SYNDROME OF PERNICIOUS LEUKOPENIA (AGRANULOCYTIC ANGINA)

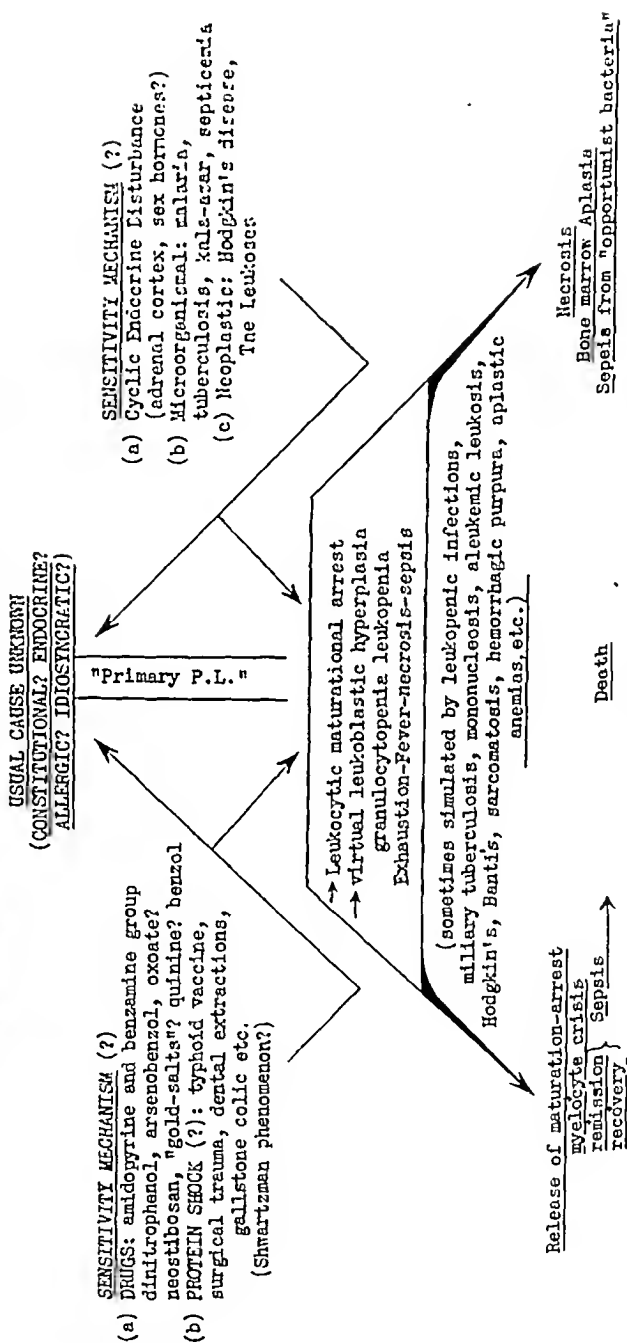

Fig. 14.

sort of clinical *reductio ad absurdum* but as long as a given disorder seems to present aspects of allergy it must be viewed as possibly genetically conditioned—in part at least.²⁸

And finally, and again *perhaps*, this may be no more than an empty restatement of the truism that all biological reactions are, in part at least, genetically conditioned.

Conclusions.—1. An hereditary basis may properly be considered along with other factors in the etiology of many of the so-called “blood diseases.”

2. The mere absence of family history of a given disorder is no proof of its nongenetic basis. Clinical (*i. e.*, apparent) atavism even in dominant anomalies is not uncommon. Atavism is almost the rule in anomalies conditioned by recessive genes.

3. The supposition or proof of a genetic basis for a given disorder does not preclude helpful therapy to the afflicted individuals nor should it be viewed as necessarily detrimental to the proper scientific attitude of investigation of other etiologic factors.

CLINIC OF DRS. GARFIELD G. DUNCAN AND
O. NORRIS SMITH

PENNSYLVANIA HOSPITAL

BOTULISM—A REPORT OF TWO SUSPECTED CASES

No greater emergency confronts the medical profession than an outbreak of botulism. The patient with signs and symptoms of this intoxication may have but remote prospects of recovery despite the best available treatment, but those treated with specific antitoxin before the onset of symptoms will recover.

Botulism (botulus—sausage) was first described in 1735¹ and was long attributed to meat, especially to sausage from Wurtemberg, a great packing center. In 1894 Van Ermenegem² isolated the spore-forming *Clostridium botulinum* from an infected ham, during an outbreak of the disease at Elezelles in which 3 of 20 patients died. This organism under anaerobic conditions was found to elaborate a virulent exotoxin, which produced typical symptoms of the disease in susceptible animals.

Outbreaks of botulism are not common. Only 6³⁻⁸ are reported in Great Britain. In America 193 outbreaks (645 cases) have been recognized between 1899 and 1932 (Beckman),⁹ more often in the West. Doubtless the majority of physicians have never seen such a patient. The 2 cases reported here were the first of the kind to be admitted to the Pennsylvania Hospital—the oldest hospital in the United States.

The general mortality rate is about 65 per cent,¹⁰ and in some outbreaks, *e. g.*, the Loch Marie tragedy, it reaches 100 per cent. Successful treatment depends on the prompt-

ness of the diagnosis. These facts and the likelihood that one may be called upon to recognize the disorder and conduct treatment without notice warrant the report of every case, in this manner keeping the subject constantly before the profession.

The *Clostridium botulinum* is widely distributed in the soil, but there is no proof that the organism or its spores are themselves pathogenic: they produce the deadly toxin only under anaerobic conditions in suitable media (most preserved foods). This toxin and the bacilli are readily destroyed by boiling but a minimal temperature of 110° C. maintained for fifteen minutes is required to kill the spores. The works of Estey and Meyer,¹¹ Dickson,¹² Leighton,³ and Lang¹³ should be consulted for further details on this subject. Botulism can be prevented by adequate pressure-cooking of preserved food, or by destruction of the toxin through boiling immediately before ingestion. Preserved food with any evidence of decomposition, *i. e.*, unnatural color, odor, or swelling of the container, should be boiled or discarded.

Most of the commercial methods for preserving foods involve sufficient cooking to destroy both the bacillus and its spores, but home-preserved foods are not ordinarily subjected to a temperature adequate for this purpose. Any sealed food container—glass, tin, wood, paraffined gauze or even the visceral covering of sausages—maintains sufficiently anaerobic conditions to allow the bacillus to produce toxin. Home canned fruits and vegetables have been the common offenders in this country, while prepared meat is the usual source of the toxin in Europe. Oddly enough, the affected food may not be distasteful, though a mild rancidity is the rule. Foods preserved in liquids may be especially poisonous. The escape of some people who have eaten such food is attributed to the absence of the toxin in that portion which lies above the fluid level in the container.

It has been claimed that the organism can elaborate the toxin within the stagnant gastro-intestinal tract; this possibility would indicate active treatment against the constipation

present in most cases. The bacilli have been found in the stool eleven days after the ingestion of the contaminated food.¹⁴ The toxin taken by mouth or introduced parenterally is highly poisonous, and is not destroyed by peptic or tryptic digestion. Alcohol is believed to have a detoxifying effect; cases have been reported in which it was taken with the poisoned food and apparently prevented fatalities.

Several strains of *Clostridium botulinum* have been identified; two ("A" and "B") are pathogenic to man. "A" toxin produces in chickens "limberneck" and death within twenty-four hours, while "B" toxin does not. The specificity of the antitoxin—unless polyvalent or mixed sera are used—makes recognition of the strain an important matter.

The cases reported below, though probably too advanced to be benefited by antitoxin when first seen, were not recognized as botulism until the postmortem examination excluded

TABLE I
SYMPTOMATOLOGY

<i>Characteristic Symptoms and Signs of Botulism</i>	<i>Case I</i>	<i>Case II</i>
Weakness or fatigue	+	+
Dizziness	+	+
Diplopia	+	+
Dilated pupils	+	+
Loss of light reflex	+	+
Ptosis of the eyelids	+	+
Paralysis of speech	+	+
Paralysis of swallowing	+	+
Dryness of the mouth	+	+
Respiratory distress	+	+
Diminished reflexes	+	+
Restless	+	+
Mental alertness	+	+
Intact sensorium	+	+
Absence of fever	slight fever	+
Elevated pulse rate	+	+
Persistent constipation	+	+

Table I.—The subjective and objective manifestations of our two patients, compared with the characteristic symptoms of botulism.

the clinical diagnosis, *vide infra*. In retrospect, the clinical manifestations and autopsy findings are in accord with the diagnosis of botulism. We are indebted to Dr. Bernard Alpers for his neurological studies of each patient.

The contents of Table I emphasize the characteristic symptoms of botulism and the parallel likeness of our 2 cases, in which the outstanding symptoms were dizziness, diplopia, ptosis of the eyelids, paralysis of speech and swallowing and persistent constipation. The low or absent fever with an elevated pulse rate, the mental alertness and the intact sensorium with the rapidly progressing palsies were also striking.

Dickson¹⁵ has concisely presented the clinical picture of botulism in the following words—"A sensation of weakness and fatigue, vertigo, uncertain gate, muscular weakness, blepharoptosis, mydriasis, loss of pupillary reflexes to light, diplopia, dryness of mouth, difficulty in talking and swallowing, persistent constipation, normal or subnormal temperature, with rapid pulse, intact skeletal reflexes and absence of mental or sensory dulness are all characteristic signs of botulism and together constitute a clinical picture, which, once seen, cannot be forgotten.

"The condition which is most closely resembled is belladonna poisoning.

"The onset of symptoms varies from a few hours to several days after the toxin is ingested—in a series of 200 cases a few within twelve hours, 74 per cent within forty-eight hours and all but 8 within four days."

Case I.—B. P., a sixteen-year-old Italian stenographer, was admitted to Dr. T. McCrae's service on January 5, 1934. The history was obtained in writing, as she was unable to talk. Her chief complaints included drooping of the eyelids, flashes of light before the eyes, dimness of vision, dryness of the mouth, difficulty in swallowing, and inability to use her tongue properly.

Family History.—One brother (Case II) was examined the same day because of vertigo, and another brother of three

years was ill at home with an acute respiratory infection. The patient's mother had had some stiffness and swelling of the neck with a sore throat and malaise on January 1st and 2nd. Eight siblings living in the same house were entirely well. A package of freshly gathered mushrooms was consumed on January 1st, chiefly by the father without ill effect, while several of the children, including both patients, had eaten small portions.

Past Illnesses.—Measles in early childhood, scarlet fever and diphtheria at five, acute tonsillitis at ten, and tonsillectomy at thirteen.

Present Illness.—The patient was intelligent and cooperative, and was well prior to this illness. On January 2nd, after eating a "wiener" at a lunch counter (10 A.M.) she had epigastric discomfort and was nauseated. Her eyes felt heavy, and by evening she could hardly keep them open, though she was not drowsy, and lights appeared extremely bright. Her vision was dimmed so that she was unable to read, but she could recognize people and distinguish colors.

Next morning (January 3rd), she had diplopia and her throat felt "stiff." Liquid foods regurgitated through her nose, and solid food stuck in her throat. On the morning of January 4th, she had a mild headache; her vision was greatly impaired and diplopia was marked; she could no longer identify colors or details; swallowing was extremely difficult, and she could neither articulate, clear her throat, nor cough effectively. Subjectively, her tongue seemed hard, shortened and stiff.

When admitted on January 5th, having had no previous medical attention, she complained of the following additional symptoms; inability to grip objects firmly, general sense of weakness and fatigue. She could walk only with support. Her appetite was good; she had been unable to eat for two days because of choking. Her bowels had not moved on the second and third days of her illness, but on the fourth day just before hospitalization, she had had a small, difficult movement—the only evacuation during her sickness. This stool was not available for the examinations suggested below.

Physical Examination.—(January 5th, 8 P. M.) Patient comfortable, nutrition and color good, cheeks flushed, skin dry, rectal temperature 99.1° F., and pulse rate 124. The marked ptosis of both upper lids gave her a lethargic appearance, though she was mentally alert and keenly aware that she was seriously ill. Her vision and speech were greatly impaired, her voice had a nasal tone, and she was unable to swallow or clear her throat. The eyelids could be closed firmly, but could not be elevated. The pupils were widely dilated; direct and crossed light reflexes were present but diminished; the eyes could not be externally rotated and there was slight reddening of the right optic disk. She was unable to wrinkle her forehead, and there was diminished retraction of the angles of the mouth upon deliberate effort to smile. She could not purse the lips, whistle, or open her mouth widely, though she could clench her teeth firmly. Protrusion of the tongue was limited, and she was unable to touch the angles of the mouth with the tip of the tongue. Mucus accumulated in the oropharynx as she could neither swallow nor expel it. The pharyngeal and palatine reflexes were absent. At this time the neck muscles were not weak, and shrugging of the shoulders was possible. The tendon reflexes were active. Both hand grips were definitely weakened. The heart, lungs and abdomen were normal to clinical examination.

At midday on January 6th, lateral deviation of the left eye occurred when a voluntary effort was made to depress it, and the masseter muscles had become definitely weakened. At 6.30 P. M., there was bilateral complete blepharoptosis; slight deviation of the left eye medially and of the right eye laterally; difficulty in depressing the right eye; limited upward movement of each orbit; inability to close the eyelids firmly but the corneal reflexes were active. There was further weakness of the facial muscles causing inability to smile, whistle, open the mouth or blow out the cheeks. The palate was immobile and the tongue could not be protruded. The hand clasps were weaker, as were the muscles of the extremities, while the biceps, triceps and Achilles reflexes were absent.

At 11.30 P. M., the patient became very restless, tossing the hands and feet about, and an hour later was incontinent of urine. The breathing became labored, cyanosis appeared, and at 1.05 A. M. (January 7th), respirations ceased abruptly; death occurred before a respirator could be utilized, approximately one hundred and eleven hours after the onset of symptoms. The pulse rate had increased steadily to 152 shortly before death, and the rectal temperatures had ranged between 99° and 100° F.

Laboratory Data.—Blood: leukocytes, 14,000; red blood corpuscles, 5,800,000; sugar 0.093 per cent; urea nitrogen, 0.016 per cent. Urinalysis: normal except for high specific gravity (1.036). Stool and gastric contents were not obtained. Lumbar puncture: pressure 7 mm. of mercury, Queckenstedt test negative, fluid slightly cloudy, cell count 4 (all lymphocytes), globulin 2 plus, sugar 0.079 per cent, Wassermann negative, colloidal gold curve normal, culture sterile, and there were no organisms found in stained smear. Cisternal puncture (postmortem): slightly cloudy fluid, globulin 2 plus, cell count 5 (all lymphocytes).

An autopsy was performed by Dr. A. Wallis and an exhaustive study of the central nervous system is being reported elsewhere.¹⁶ In brief, pathological changes were found in the anterior horn cells of the spinal cord and in the neurons of the cranial motor nuclei. Also noteworthy were the marked edema of the small and middle-sized pyramidal cells in Lamina III of the agranular cortex, and the reduction in number of small cells in the red nuclei.

Case II.—The fourteen-year-old brother (P.P.) of the first patient was admitted on January 6, 1934, to Dr. T. McCrae's service, complaining of inability to swallow, double vision, slurring of speech, dizziness, and inability to walk.

Family History.—As noted in Case I.

Past Illnesses.—Mumps, measles and "discharging ear" in early childhood, tonsillectomy at ten.

Present Illness.—The patient had been well, and attended

Physical Examination.—(January 5th, 8 P. M.) Patient comfortable, nutrition and color good, cheeks flushed, skin dry, rectal temperature 99.1° F., and pulse rate 124. The marked ptosis of both upper lids gave her a lethargic appearance, though she was mentally alert and keenly aware that she was seriously ill. Her vision and speech were greatly impaired, her voice had a nasal tone, and she was unable to swallow or clear her throat. The eyelids could be closed firmly, but could not be elevated. The pupils were widely dilated; direct and crossed light reflexes were present but diminished; the eyes could not be externally rotated and there was slight reddening of the right optic disk. She was unable to wrinkle her forehead, and there was diminished retraction of the angles of the mouth upon deliberate effort to smile. She could not purse the lips, whistle, or open her mouth widely, though she could clench her teeth firmly. Protrusion of the tongue was limited, and she was unable to touch the angles of the mouth with the tip of the tongue. Mucus accumulated in the oropharynx as she could neither swallow nor expel it. The pharyngeal and palatine reflexes were absent. At this time the neck muscles were not weak, and shrugging of the shoulders was possible. The tendon reflexes were active. Both hand grips were definitely weakened. The heart, lungs and abdomen were normal to clinical examination.

At midday on January 6th, lateral deviation of the left eye occurred when a voluntary effort was made to depress it, and the masseter muscles had become definitely weakened. At 6.30 P. M., there was bilateral complete blepharoptosis; slight deviation of the left eye medially and of the right eye laterally; difficulty in depressing the right eye; limited upward movement of each orbit; inability to close the eyelids firmly but the corneal reflexes were active. There was further weakness of the facial muscles causing inability to smile, whistle, open the mouth or blow out the cheeks. The palate was immobile and the tongue could not be protruded. The hand clasps were weaker, as were the muscles of the extremities, while the biceps, triceps and Achilles reflexes were absent.

At 11.30 P. M., the patient became very restless, tossing the hands and feet about, and an hour later was incontinent of urine. The breathing became labored, cyanosis appeared, and at 1.05 A. M. (January 7th), respirations ceased abruptly; death occurred before a respirator could be utilized, approximately one hundred and eleven hours after the onset of symptoms. The pulse rate had increased steadily to 152 shortly before death, and the rectal temperatures had ranged between 99° and 100° F.

Laboratory Data.—Blood: leukocytes, 14,000; red blood corpuscles, 5,800,000; sugar 0.093 per cent; urea nitrogen, 0.016 per cent. Urinalysis: normal except for high specific gravity (1.036). Stool and gastric contents were not obtained. Lumbar puncture: pressure 7 mm. of mercury, Queckenstedt test negative, fluid slightly cloudy, cell count 4 (all lymphocytes), globulin 2 plus, sugar 0.079 per cent, Wassermann negative, colloidal gold curve normal, culture sterile, and there were no organisms found in stained smear. Cisternal puncture (postmortem): slightly cloudy fluid, globulin 2 plus, cell count 5 (all lymphocytes).

An autopsy was performed by Dr. A. Wallis and an exhaustive study of the central nervous system is being reported elsewhere.¹⁶ In brief, pathological changes were found in the anterior horn cells of the spinal cord and in the neurons of the cranial motor nuclei. An autopsy was performed by Dr. A. Wallis and an exhaustive study of the central nervous system is being reported elsewhere.¹⁶ In brief, pathological changes were found in the anterior horn cells of the spinal cord and in the neurons of the cranial motor nuclei. Also noteworthy were the marked edema of the small and middle-sized pyramidal cells in Lamina III of the agranular cortex, and the reduction in number of small cells in the red nuclei.

Case II.—The fourteen-year-old brother (P.P.) of the first patient was admitted on January 6, 1934, to Dr. T. McCrae's service, complaining of inability to swallow, double vision, slurring of speech, dizziness, and inability to walk.

Family History.—As noted in Case I.

Past Illnesses.—Mumps, measles and "discharging ear" in early childhood, tonsillectomy at ten.

Present Illness.—The patient had been well, and attended

school on January 4th, but upon awakening at 6:30 A. M. next morning he experienced marked vertigo on standing. He returned to bed after eating breakfast. At 10 A. M., with no improvement, he visited the hospital, reporting also that his eyes were "hurting." The only positive finding on a careful physical examination was a mild conjunctivitis, but because of the vertigo he was kept at rest under observation until 5 P. M., when he was sent home with no new developments. That evening he vomited—an ill omen. He slept well but when awakened at 8 A. M. (January 6th) was unable to rise because of extreme vertigo. His eyes "hurt" slightly, there was lacrimation, and he could not swallow. He was returned to the hospital by ambulance. Nothing unusual about his diet could be determined, except for the mushrooms (*vide supra*) eaten January 1st.

Physical Examination (January 6th).—The patient was conscious and mentally alert; rectal temperature 99° F., pulse rate 115, blood pressure 126/104. There were present bilateral blepharoptosis (more marked on the left), mydriasis, diminished pupillary response to light, complete ophthalmoplegia and active corneal reflexes. The right corner of the mouth drooped slightly, but he was able to wrinkle the forehead and close the eyes firmly. The soft palate was completely immobile, and the tongue could be weakly protruded in the midline. Cutaneous perception of pain was normal. The hand clasps were weakened, but the power in the arms and legs was good; there was no incoordination, no muscular twitchings, and no convulsive movements. The biceps, triceps and patellar reflexes were active and equal; the heel-to-heel test was accurately performed. There was no characteristic Babinski sign on plantar stimulation, though all toes and the ankle were extended. The sensations of position, vibration and pain were intact. There was no stiffness of the neck, and no Kernig's sign. The abdominal and cremasteric reflexes were active but easily fatigued.

At this time the neurological signs were largely confined to the cranial nerves, especially the third, fourth, sixth, tenth,

and twelfth, with partial involvement of the seventh. There were no signs of meningeal irritation. The process indicated involvement of the base of the brain, especially the nuclei of the cranial nerves mentioned. Encephalitis, an abortive type of anterior poliomyelitis, or some intoxication were considered as possible causes.

January 7th.—Ptosis of the eyelids was almost complete; there was definite palsy of the muscles supplied by the seventh nerves, coupled with inability to wrinkle the forehead; he could open his mouth slightly, but could not retract the corners; the masseter muscles were active. The tongue was weaker—he could protrude only the tip and it deviated slightly to the right. Thoracic excursion was diminished, and respiration was abdominal in character. There was no weakness of the leg muscles. The abdominal and biceps reflexes were absent. The patellar reflexes responded only to repeated stimulation. There were no sensory changes. These signs suggested a progressive involvement of the spinal cord as well as the bulbar region.

On the morning of January 7th, the patient became cyanosed and the respiration more feeble. He was placed in the respirator, but the improvement was temporary. Death followed shortly, eighty hours after onset of symptoms. The pulse rate had increased to 132 before death, and the highest rectal temperature was 99.2° F. There was no bowel movement during his hospital stay. The patient's mental alertness was a striking contrast to his lethargic appearance, and persisted almost to the end. An autopsy was not permitted.

Comments.—Both patients had eaten mushrooms—as had the father who remained well—on January 1st. The onset of illness in Case I was about 10 A. M. January 2nd, and in Case II, 6.30 A. M. January 5th. The delayed onset of symptoms, the escape of the father, and the autopsy findings exclude mycetismus.

The first patient had eaten a "wiener" but her brother had not. The mother insisted that her own illness was an "ordi-

nary sore throat," and the infant brother, hospitalized elsewhere, had an acute upper respiratory infection.

That only two members of a large family should be poisoned, apparently on different days, suggests that probably the greater part of the noxious food was free of the toxin. This possibility has been stressed in another instance by McCaskey.¹⁷ All members of the family had allegedly partaken of the same foods, except as noted above. Efforts to identify the source of the toxin were unsuccessful.

Diagnosis.—Encephalitis and mushroom poisoning were discarded in favor of anterior poliomyelitis of the bulbar type, despite the season of the year, and the simultaneous occurrence in siblings. Botulism was discussed, but the symptoms were considered in accord with acute bulbar poliomyelitis. This decision was finally reversed by exclusion of the latter at autopsy, and we are convinced that these were typical cases of botulism, though lacking bacteriological support of this diagnosis.

For completeness, it should be mentioned that cerebrospinal syphilis, toxic ophthalmoplegia, rabies, postdiphtheritic complications, poisoning with belladonna or methyl salicylate, and atypical Landry's paralysis may be confused with botulism.

The investigation and treatment, in retrospect, were incomplete; hence we present in more detail an outline of more adequate study of suspected cases of botulism.

A. General.—1. Obtain the assistance of municipal and state Boards of Health for an epidemiological survey, prophylactic immunization of other contacts, securing of antitoxin, etc.

2. By careful review of the diet, identify and, if possible, procure a sample of the responsible food for laboratory examination.

3. All other persons who ate the suspected food should be given immunizing doses of mixed antitoxin sera—2000 units of type A and 2000 units of type B—subcutaneously after testing for sensitivity.

4. If the responsible food has been commercially prepared, the manufacturer should be notified at once in order that other contaminated foods may be recalled. Suspected food may be rendered safe for further storage by adequate pressure cooking, or for ingestion by boiling immediately before consumption.

B. **Specific.**—1. The patient's stool and vomitus, as well as suspected foodstuffs, should be subjected to microscopic search for the organism in the stained smears, and to bacteriological cultures in anaerobic glucose media.

2. Inoculation of guinea-pigs, or preferably mice, with filtered aqueous solutions of food, vomitus, feces or intestinal washings containing the toxin will promptly reproduce the clinical manifestations as seen in man. Mice inoculated intraperitoneally will usually die within six hours. By giving one mouse the toxin alone, a second mouse toxin with type A antitoxin, and a third mouse toxin plus type B antitoxin, the specific serum may be quickly selected, and the strain of organism identified.

3. Chickens fed on the toxic material will develop "limber-neck" only if type A toxin be present, being refractory to type B toxin.¹⁵

4. Isolation of the toxin from the patient's blood is feasible. Citrated blood may be injected intraperitoneally into animals for this purpose.¹⁹ Bergman *et al.*²⁰ identified the toxin in the blood of several patients by toxin-antitoxin experiments of this character.

5. At autopsy, the bacillus is most likely to be demonstrated in the brain,²¹ spleen²² and jejunal wall.¹⁴

C. **Treatment.**—1. **Antitoxin.** Before the strain is identified, 10,000 units of mixed (A and B) antitoxin sera should be given intramuscularly after preliminary testing for serum sensitivity; the same dosage of univalent serum is subsequently administered at twenty-four-hour intervals. If given before the toxin is fixed in the tissues, *i. e.*, before the onset of symptoms, the prognosis is good; otherwise it does not appear to alter the course of the disease, but even after symptoms appear,

it will neutralize the toxin present in the blood, or subsequently absorbed from the intestinal tract.

Botulinus antitoxin may be obtained from the Jensen & Salisbury Laboratory, Inc., Kansas City, Mo.; from the Hygienic Laboratory, Washington, D. C.; and from the Department of Health, New York City.

2. Absolute rest. The patient should be kept under the influence of morphine or sodium amytal after the diagnosis is made.

3. Diet. Liquids should be given freely with adequate calories (30 per kilogram of body weight) by nasal tube left *in situ*.

4. Gastric lavage. This is recommended if the patient is seen early. Oleum ricini, 1½ ounces, or magnesium sulphate, 1 ounce, may be left in the stomach.

5. Enemata. Early evacuation of the intestinal tract is highly desirable.

6. Artificial respiration. Respirations may cease with little warning. The slightest signs of respiratory embarrassment indicate "respirator" treatment.

CLINIC OF DR. JOHN DURKIN

METABOLIC CLINIC, PENNSYLVANIA HOSPITAL

DIABETES MELLITUS AND HYPOTHYROIDISM WITH A REPORT OF A CASE

DIABETES mellitus complicated by hypothyroidism is rare and there is but a small literature on this subject. This is in contrast to 1.1 per cent of all patients with hyperthyroidism who have true diabetes (Wilder¹).

Joslin³ reported a case of myxedema with subsequent development of diabetes. The diabetes was readily controlled by dietetic treatment. Thyroid medication was continued by the patient according to her symptoms for eighteen months. During this time the diabetes seemed to become more severe. Hospitalization and insulin treatment were refused. Nevertheless a moderate diet prevented glycosuria. The basal metabolic rates varied from -32 per cent before to $+14$ and -9 per cent after the onset of diabetes and during thyroid therapy. Another case³ cited had diabetes for eleven years before the onset of myxedema. Basal metabolic determinations in this instance averaged -20 per cent.

Holst² reported an improved tolerance for glucose in a diabetic who developed myxedema following thyroidectomy for exophthalmic goiter. Wilder¹ records improvement in tolerance in a diabetic child, aged three years, coincident with the development of myxedema. Growth was resumed but intense glycosuria and ketosis followed thyroid therapy. Growth ceased and the tolerance improved when thyroid treatment was stopped. This was so striking that the patient

CLINIC OF DR. JOHN DURKIN

METABOLIC CLINIC, PENNSYLVANIA HOSPITAL

DIABETES MELLITUS AND HYPOTHYROIDISM WITH A REPORT OF A CASE

DIABETES mellitus complicated by hypothyroidism is rare and there is but a small literature on this subject. This is in contrast to 1.1 per cent of all patients with hyperthyroidism who have true diabetes (Wilder¹).

Joslin³ reported a case of myxedema with subsequent development of diabetes. The diabetes was readily controlled by dietetic treatment. Thyroid medication was continued by the patient according to her symptoms for eighteen months. During this time the diabetes seemed to become more severe. Hospitalization and insulin treatment were refused. Nevertheless a moderate diet prevented glycosuria. The basal metabolic rates varied from -32 per cent before to $+14$ and -9 per cent after the onset of diabetes and during thyroid therapy. Another case⁸ cited had diabetes for eleven years before the onset of myxedema. Basal metabolic determinations in this instance averaged -20 per cent.

Holst² reported an improved tolerance for glucose in a diabetic who developed myxedema following thyroidectomy for exophthalmic goiter. Wilder¹ records improvement in tolerance in a diabetic child, aged three years, coincident with the development of myxedema. Growth was resumed but intense glycosuria and ketosis followed thyroid therapy. Growth ceased and the tolerance improved when thyroid treatment was stopped. This was so striking that the patient

"could eat anything without excreting sugar." The child presented the appearance of juvenile myxedema, "the face dull and expressionless, the skin dry and thick, the hair coarse and scanty." The mentality and physical development were much retarded with a B. M. R. of -45 per cent. There was no glycosuria and the blood sugar was 0.12 per cent. Thyroid extract was again administered in small doses and the metabolism raised gradually. The diet was rigidly restricted. When the B. M. R. reached -10 per cent sugar appeared in the urine. Glycosuria continued—as much as 20 Gm. daily—and the fasting blood sugar reached 0.145 per cent, in spite of 10 units of insulin daily. This case, according to Wilder, lends support to the theory that with lower metabolic rates the tissue cells can utilize a given amount of glucose with less insulin than when the metabolism is at a higher rate.

Wright⁴ presented 2 cases of myxedema and diabetes in which, contrary to the accepted theory, the administration of thyroid extract had no untoward effect on the action of insulin.

Case Report.—W. C., female, age thirty-eight, a servant, was admitted to the Pennsylvania Hospital October 14, 1935, complaining of: a craving for sweets, itching about the vulva, dizziness, flashes of light before her eyes, headache, constipation, loss of weight, frequent urination with nocturia and burning on urination, numbness, tingling in the legs and painful fingers.

The family history was irrelevant and her past illnesses consisted of scarlet fever, whooping cough and measles in childhood, pleurisy in 1917, influenza in 1918 and erysipelas in 1922. Her best weight was 82.7 Kg. (182 pounds) in 1925; she has had excessive thirst for many years and recently she has slept poorly.

Present Illness.—On August 27, 1935, rising to void at night, she became dizzy and fell, striking her head. Frontal headache and vertigo have been constant symptoms since. Increased appetite, frequency of urination, with large quantities of urine have been noted for many years but on September

23, 1935, she first noticed pruritus vulvae. This has persisted. Glycosuria was detected on October 10 and the blood sugar was 265 mg.

Physical Examination.—The points of note were: height, 62 inches; weight, 71.8 Kg. (158 pounds); blood pressure, 170/95; patient short and stout with some fulness of neck. Skin thickened. Left border of cardiac dullness 12 cm. from the midsternal line in the fifth costal interspace. Soft systolic murmur at the apex. Pulmonic second sound greater than the aortic second. Abdomen moderately obese.

Laboratory Data: see table, pages 282, 283.

Discussion.—This patient presented the appearance of having a moderately severe diabetes complicated by hypothyroidism. The diabetes, before standardization, was sufficiently severe to cause a loss of weight in spite of a low metabolism, the basal metabolic rate being -27 per cent. Subsequently when the diabetes was controlled there was no loss of weight with a diet of 1100 calories. Following thyroid therapy, however, a decrease in weight ensued. During this treatment the diet and insulin were kept practically constant, the insulin averaging approximately 35 units daily. The blood sugar values varied from 0.265 to 0.08 per cent, and the weight steadily decreased from 155 pounds to $137\frac{1}{2}$ pounds. The basal metabolic rate reached $+31$ per cent. At this point it was decided to stop the thyroid medication and note the changes that ensued. In three months the weight increased to 150 pounds, higher than at the time of admission to the ward. The insulin was gradually decreased as the basal rate returned to the former level, the blood sugar dropped to normal, and the urine became practically sugar free. It would appear that on a continued restricted diet (1100 calories) this individual should be able to maintain her weight at about 150 pounds, and also remain fairly well standardized unless some factor such as an infection, thyroid therapy, pregnancy, fever or intoxication should complicate the picture. Any of these would elevate the metabolism and consequently larger amounts of insulin would be necessary.

Conclusion.—This case serves to illustrate that by increasing the total metabolism with thyroid, the diabetes is made more severe. This has been noted by others.^{5, 6, 7} When thyroid was stopped, the basal metabolism and in consequence the total metabolism was lowered and the diabetes appeared less severe and was more easily controlled.

CLINIC OF DR. MICHAEL G. WOHL

TEMPLE UNIVERSITY AND PHILADELPHIA GENERAL HOSPITALS

HYPERTHYROIDISM

AN EVALUATION OF BLOOD IODINE, IMPEDANCE ANGLE AND BASAL METABOLIC RATE IN BORDERLINE CASES

IN a survey of the hyperthyroid syndrome,* certain basic facts should be borne in mind. First—while one is impressed at the bedside that many symptoms of Graves' disease may be attributed to other glands of internal secretion than the thyroid, such as the adrenal glands, the pituitary, etc., the fact remains that when the surgeon fails to remove sufficient thyroid tissue the patient will return after a certain interval of time with symptoms of hyperthyroidism, and when sufficient thyroid tissue is removed the second time, the symptoms will largely disappear. Therein lies a fact which is difficult to reconcile with Zondek's¹ so-called "peripheral theory" of the pathogenesis of Graves' disease. The recent follow-up study by Thomas and Rienhoff² of patients who were operated on for hyperthyroidism by removal of approximately nine tenths of the thyroid gland, shows that over 90 per cent of the cases were completely rid of their symptoms. The histological picture of the thyroid tissue was that of hyperplasia and hypertrophy. Then again patients dying of hyperthyroidism show, as the most outstanding anatomic finding, alterations in the thyroid gland almost to the exclusion of other organs. Even the enlargement of the thymus is not a constant finding, being pres-

* For practical purposes the term "hyperthyroidism" includes Graves' disease or the toxic diffuse goiter as well as toxic adenoma or the toxic nodular goiter.

ent in only 15 per cent of the cases; and the structural changes in the liver in the form of well-marked hepatitis occurs only in about 54 per cent of cases.³ Attempts to produce hyperthyroidism in man by injection of thyrotropic hormone of the anterior pituitary have been disappointing, although in animals this hormone is capable of producing hyperplasia of the thyroid, rise in metabolism and loss of weight.⁴

One therefore is forced to conclude that hyperthyroidism in man is associated with hyperplasia of the thyroid and that the removal of the greater part of the thyroid gland offers the best therapeutic approach today as it will result, in a great majority of patients, in a marked clinical improvement or cure.

The second fact to be considered is that the inherent capacity of tissues to respond to the thyroid stimulation varies in different individuals. This may explain why in some patients suffering from hyperthyroidism the outstanding symptoms will be referable to the cardiac and in others to the gastro-intestinal and in still another group of patients to the nervous system. This phase will be discussed in some detail later.

From a diagnostic point of view it is important to stress the fact that the outstanding physiological abnormality of hyperthyroidism is the derangement of the regulatory control of tissue oxidation. This is measured by the determination of the basal metabolic rate. Thyroid activity may be judged by another method. The thyroid gland functions as a regulator of iodine metabolism. The thyroid hormone, thyroxin, is high in its iodine content. It is apparent then that the level of blood iodine and the amount of iodine excreted in the urine may serve as a diagnostic aid in evaluating thyroid activity.⁵ A similar analogy one finds in evaluating pancreatic function by the blood sugar level and the amount of sugar excreted in the urine. The average normal blood iodine content found by Mr. Charles Goss in my laboratory on a group of 15 patients without evidence of thyroid disease was 11 gamma per 100 cc. of blood (a gamma or microgram is 0.001 mg.). In 18 patients with toxic goiter, including both the diffuse and nodular

type, the blood iodine varied from 15 to 39 gamma; the basal metabolic rate ranged in these patients from plus 24 to plus 56 per cent. Similar observations have been made by other workers. It is interesting that no correlation between the clinical severity of the disease, the basal metabolic rate and the concentration of blood iodine was noted. One must also bear in mind the fact that in some patients there may be an abnormally high excretion of iodine and therefore the blood iodine level may remain normal (a negative iodine balance).

During the progress of these studies it was my impression that the method for blood iodine determination was too complicated and time consuming to prove of practical importance in the diagnosis of hyperthyroidism.* Dr. D. Roy McCullagh⁶ of Cleveland has described a method which appears to be relatively simple and accurate. I personally had no experience with it.

Recently a bioelectric method for diagnosis of hyperthyroidism has attracted attention. This procedure is designated by Brazier⁷ as the determination of the impedance angle, and by Lueg,⁸ Wohl⁹ and others, as the polarization capacity of the skin. While, for the impedance angle, high frequency alternating current (20,000 cycles) is used, it is important to point out that the quantities measured by the different workers are closely related to the impedance of the body to an alternating current passed through the body.¹⁰ Brazier found that "in thyrotoxicosis there is a very marked deviation from the normal, these cases giving very high values for the impedance angle." She also found that the severer the disease the higher the impedance angle. On the other hand we found that the polarization capacity of the skin was not correlated with the basal metabolic rate in every instance. After working on this problem for two years I feel that the method is pregnant with too many technical difficulties to prove of clinical value, especially in the borderline cases. Dr. Lahey in a personal communication to the author writes: "we have had as high

as 29 per cent error in the cases of hyperthyroidism" (using the impedance angle).

For practical purposes the diagnosis of hyperthyroidism is to be made from the clinical manifestations of the patient and a marked rise in the basal metabolic rate. The classical symptoms of hyperthyroidism are appreciated by all of us. They are: loss of weight in spite of increased energy intake, loss of strength, hypersensitiveness to heat, the persistent tachycardia and the characteristic emotionalism; irritability and restlessness. The atypical case of hyperthyroidism presents difficulties in diagnosis because of its protean symptomatology which may mimic organic disease of the heart, gastro-intestinal disturbance and because the basal metabolic rate may not be within the expected range. An increase in the basal rate is generally accepted as an indication of a thyrotoxic state. It should be borne in mind, however, that there is a small group of patients with hyperthyroidism, whose basal rate remains normal. This might be explained as due to the fact that the test is taken during the quiescent period, either as the result of a spontaneous or an iodine remission. Again, there are persons who have normally a lower basal rate, and therefore a rate that would be considered normal in another individual, might indicate thyrotoxicosis in such a person. In one of our cases of hyperthyroidism, masked as paroxysmal tachycardia, the basal rates were plus 7, plus 9, plus 3 and minus 12. A thyroidectomy brought about an amelioration of the symptoms that differed in no way from that in thyroidectomized patients with similar symptoms and a high basal rate. This patient belonged to a group to whom operation has been denied, due to overestimation of the importance of the metabolic rate.¹¹ A similar experience was described by Morris.¹² One should, however, be cautious in diagnosing hyperthyroidism in a patient who has a normal rate; other signs of hyperthyroidism are to be carefully looked for in the confirmation of the diagnosis.

Some patients with tuberculosis, essential hypertension and cardiac decompensation may present confusing points of

similarity with hyperthyroidism. It is to be borne in mind that the basal rate determination may not prove of great help in these conditions, since it is frequently elevated. Thus in pulmonary tuberculosis (advanced) the basal rate may be as high as plus 30 per cent. In early tuberculosis, however, the basal rate is normal.¹³

It may be impossible at times to decide whether one deals with early hyperthyroidism or malignant hypertension. The tachycardia, loss of weight, and muscle weakness are not uncommon in hypertension. Still greater confusion may arise when there is a fulness of the eyeballs which may simulate exophthalmos. One patient in our series presented such a picture; and even after six weeks of close observation, it was extremely difficult to make a differential diagnosis.¹⁴ The basal metabolic rate may not be of much help in such a case since in hypertension the basal metabolic rate may be elevated.¹⁵ A high diastolic blood pressure is usually found in hypertension and not in hyperthyroidism. This point might prove of value in the differential diagnosis.

A useful procedure in establishing the diagnosis in cases with an elevated basal rate is to observe the specific effect of Lugol's solution.¹⁶ A series of metabolic tests is made before iodine is administered. This is done in order to detect a possible drop as the result of the patient's training in taking the tests. On about the eighth day of treatment, a most characteristic drop in the basal rate occurs if the patient suffers from hyperthyroidism; the clinical status may not be noticeably improved. After iodine is discontinued there is a rise in the rate after some interval. This is almost conclusive evidence of hyperthyroidism.

Another group of patients in whom the basal metabolic rate is often elevated are persons suffering with cardiac decompensation. It may become necessary to decide whether the high basal rate may be due to a possible hyperthyroidism being the cause of the cardiac disturbance. The average increase in the basal rate in cardiac decompensation without hyperthyroidism, is said to be 39 per cent above normal.

In a group of 38 cases studied at the Philadelphia General Hospital, Dr. Harold Robertson and I found the average basal rate to be plus 30. In one of our patients with cardiac decompensation due to mitral stenosis and insufficiency, the basal rate during the period of decompensation averaged plus 26 per cent. After nine days of restoration of compensation, it came down to plus 5 per cent. An increase of the basal rate above 30 per cent should be considered as due to hyperthyroidism, rather than to cardiac decompensation unless dyspnea is very marked.

The most bothersome condition to be distinguished from hyperthyroidism is that of autonomic imbalance, especially when there is present a goiter, tremor, and loss of weight. Such conditions have often been erroneously classified as *formes frustes*. "Such patients," as McGregor puts it, "are so often the victims of overenthusiastic specialism, that they present the greatest goiter problem of today." I have been able to follow a number of such patients who have been operated upon, and in whom the results were disappointing.

It is apparent that treatment for "toxic goiter" in such patients does not lead to symptomatic cure. There is no patient for whom a thyroidectomy will do more harm than cases of this type; an unnecessary operation will often overthrow an already poorly balanced nervous system. The autonomic imbalance cases are closely associated with the asthenic constitution of Stiller, orthostatic albuminuria or *cor juvenum* (Chvostek). They frequently present cardiovascular complaints without any demonstrable cardiovascular pathology and symptoms of functional neurosis are constantly present. Thus palpitation, dyspnea, precordial discomfort, ready fatigability, faintness, vertigo, insomnia, increased perspiration, difficulty in swallowing, tremor, pallor and flushing are all too familiar symptoms that patients with autonomic imbalance present for a long time. They differ from cases of *formes frustes*, and the monosymptomatic hyperthyroidism in that there is no elevation of the basal metabolic rate and persistent tachycardia does not occur. The tachycardia is an out-

standing and constant feature of hyperthyroidism, and is present even during sleep. Boas¹⁷ has recorded, with cardiometer, waking and sleeping heart rates in patients with hyperthyroidism, and in persons with neurogenic sinus tachycardia. He found that although during waking hours the heart rate of persons with neurogenic tachycardia approximates that of patients with Graves' disease, during sleep there is a distinct reduction of the heart rate, reaching minimum levels that approach those of normal (the minimum heart rate for males being 53 and that of females 58 per minute), while in hyperthyroidism there is little reduction of the heart rate during sleep.

A point of some importance is that the patient with neurocirculatory asthenia is apt to complain of symptoms regarding his neck, which symptoms may have been suggested to him. Thus, three such patients were referred to us from the Jackson clinic because of the feeling of constriction and difficulty in swallowing. Fluoroscopic and esophagosopic examinations showed no abnormal findings in the pharynx and esophagus. The hyperthyroid patient on the other hand rarely complains of a choking sensation. He usually gives a history of having been in good health until his present illness for which he seeks medical advice. He is hyperactive, optimistic as to his ability to do things, although he is soon forced to stop his work because of fatigue.

There are a number of patients suffering from hyperthyroidism many of whom are treated for something else with disastrous results. The reason for the erroneous diagnosis is that such patients have a paucity of pathognomonic signs of hyperthyroidism. Their symptoms are referable to gastrointestinal or cardiac system and unless one is goiter minded the diagnosis of hyperthyroidism is often overlooked.

I have reported a group of patients in whom the common denominator was heart disease and who were treated for auricular fibrillation, paroxysmal tachycardia, congestive heart failure, transient auricular flutter, angina pectoris respectively; the hyperthyroid syndrome was never predominant; indeed

they mimicked organic heart disease to such an extent that they were treated for months by the usual cardiac therapy of rest, sedatives and digitalis without improvement. Not until the real trouble was suspected to lie in the thyroid gland and compound solution of iodine, x-ray or thyroidectomy was instituted were they relieved of their symptoms.^{11, 14, 18}

In one patient the symptoms of hyperthyroidism were masked as a spastic colitis. This latter case is of special interest to us since Drs. Wm. Egbert and Harold F. Robertson and I have observed three other patients with hyperthyroidism in whom abdominal symptoms simulating acute surgical catastrophe were noted. This latter observation will be the subject of a future presentation.

Another one of our patients was treated for angioneurotic edema of the eyelids and one patient was attending a diabetic clinic for two years and failed to respond to insulin therapy as anticipated. One patient developed an amenorrhea and vague nervous disturbances and was treated for essential hypertension. In one male patient impotence was the most outstanding initial symptom. The patient was treated for three months before the true nature of the condition was recognized. The cardinal signs of exophthalmic goiter in all of them were few or absent.

In the final analysis the diagnosis of hyperthyroidism will largely rest on the observer's judgment as to all the signs and symptoms and his experience with similar patients.

CLINIC OF DR. BERNARD I. COMROE

MEDICAL CLINIC OF THE HOSPITAL OF THE UNIVERSITY OF
PENNSYLVANIA

DIAGNOSIS OF DISEASES ASSOCIATED WITH EN- LARGEMENT OF THE LIVER OR SPLEEN

IN this discussion an attempt is made to point out the most probable causes of enlargements of the liver and spleen and to present the diagnostic procedures which have proved of most value.

An enlarged liver is usually easily palpated with the patient lying flat on his back, and the abdominal wall further relaxed by flexion of the knees. Muscular relaxation is sometimes obtained only after immersing the patient in a tub of warm water. The liver is generally felt most readily just outside the edge of the right rectus muscle. When the lower margin is palpated, one must not conclude that this organ is enlarged until he has determined by percussion that the upper border is in its usual position. In thin, ptotic individuals it is not unusual to find that the upper border of a liver coincides with the costal margin. Again, in patients with liver abscess, the enlargement of the liver may be chiefly upward. A normal sized liver may be displaced downward by pulmonary emphysema, pleural effusion, or subdiaphragmatic abscess; on the other hand, pathological lesions which may be confused with an enlarged liver include carcinoma of the stomach, especially with infiltration along the greater curvature, impacted feces or malignancy of the transverse colon, or a greatly

thickened omentum secondary to chronic inflammatory or neoplastic peritonitis; as all of these are directly or indirectly attached to the liver, they may also move with respiration.

The overlooking of a splenic enlargement is most often due to hasty and improper examination for this organ. Most individuals agree that the patient should be examined first while lying flat on his back, with the knees well drawn up, the abdomen exposed, the palpating hands warm, and one hand used posteriorly to exert upward pressure while the other hand attempts to feel the splenic edge slip from under the left costal margin during a deep inspiration. Several additional points may prove useful. The lower pole of a greatly enlarged spleen may be felt low in the abdomen, and not under the costal margin; a spleen not formerly felt may become palpable when the patient assumes the right lateral decubitus with the knees well drawn up. Some of the characteristics of an enlarged spleen are as follows: the examining fingers can not be passed between the enlarged mass and the left costal margin; one or more well-defined notches may often be felt on its lower mesial border; percussion will reveal that the dulness over the enlarged mass is continuous with the dulness over the splenic area in the ninth to the eleventh interspaces in the left mid-axillary line; with a certain amount of practice, the dulness over the normal spleen can often be percussed so that slight enlargements of this organ may be detected before the mass becomes large enough to be palpated. The descending colon does not lie in front of an enlarged spleen. This latter can be determined by percussion alone, or by percussion after insufflation of the colon with a small amount of air. A markedly enlarged spleen will usually cross the midline below the umbilicus.

Of the many tests of liver function, very few are of real value in differential diagnosis. With the exception of the van den Bergh reaction, little diagnostic aid is obtained from these; on occasions, the bromsulphalein dye test and the galactose tolerance test have been of slight assistance. The Takata-Ara reaction for the diagnosis of portal cirrhosis is not positive

until a late stage of the disease so that its use is quite limited. The multiple functions performed by the liver render it practically impossible for any one test to properly evaluate the amount or type of damage to that organ. In regard to splenic function, no test is yet available; possibly further work along the line of radiopaque media such as thorotrast may offer some lead in this direction.

Bleyer¹ has shown that slight enlargement of the spleen is common in apparently healthy infants and is thus of little or no diagnostic help at this time. He found the spleen to be enlarged in 8 per cent of infants up to the third month, in 25 per cent from the third to the ninth month, in almost 20 per cent during the remainder of the first year, and in 9 per cent during the second year. He also pointed out the frequency of an enlarged spleen in childhood infections (measles, pneumonia, pertussis, syphilis, otitis media, tonsillitis, rickets, impetigo, rubella, eczema) and emphasized the infrequency of such an enlargement in so-called "simple" malnutrition. In an examination of the autopsy records of 14,000 patients, Barron and Litman² found that the diseases most frequently accompanied by marked splenic enlargement (of 600 Gm. or over) in adults were: leukemia, subacute bacterial endocarditis, portal cirrhosis, and Hodgkin's disease. Of spleens weighing 1400 Gm. or over, practically 80 per cent were found in patients diagnosed leukemia. They also found that the commonest causes of definite palpable enlargement of both liver and spleen in adults were: leukemia, gumma, subacute bacterial endocarditis, puerperal sepsis, typhoid fever, Hodgkin's disease, and portal cirrhosis. Concerning the frequency with which these diseases are encountered in the hospital wards, during the past two years there have been admitted to the medical clinic 23 patients with Hodgkin's disease, 21 with leukemia, 21 with portal cirrhosis, 18 with pernicious anemia, and 14 with subacute bacterial endocarditis.

A table attempting to classify the causes of hepatic enlargements is as follows:

HEPATIC ENLARGEMENTS

I. *Cardiac Decomensation.*

II. *Cirrheses* (portal, toxic, obstructive biliary, luetic, carcinomatous, hypertrophic biliary—Hanot's, polyorrho-menitis multiple serositis, Banti's syndrome, hemo-chromatosis, eclamptic, carbon).

III. *Tumors*

A. *Benign* (adenoma, angioma, cavernoma, lymphangioma, myxoma, fibroma, lipoma).

B. *Malignant* (carcinoma, melanosarcoma, chorionepithelioma, sympathetic neuroblastoma, teratoma, embryoma).

C. *Cysts* (blood and degenerative, dermoid, endo-thelial, hydatid, lymphatic, etc.).

IV. *Inflammations*

A. Acute pylephlebitis.

B. Hepatitis (septicemia, Weil's disease, relapsing fever, yellow fever, secondary syphilis, arsenicals, chloroform, phosphorus, pennyroyal, extract of male fern, naphthol, potassium chlorate, arseniureted hydrogen, atophan (cinchophen), mushroom poisoning, tuberculous, schistosomiasis, streptococcic, etc.).

C. Abscess (single, multiple, amebic).

D. Syphilis, malaria, typhoid fever, actinomycosis, kala-azar.

E. Slight enlargement, cloudy swelling, may occur in any septic disease.

V. *Blood Dyscrasias*

A. Leukemia.

D. Pernicious anemia.

B. Hodgkin's disease.

E. Sick cell anemia.

C. Hemolytic icterus.

F. Polycythemia.

VI. *Metabolic*

A. Gaucher's disease.

B. Niemann-Pick's disease.

C. Amyloidosis.

D. Von Gierke's disease.

E. Fatty liver.

F. Diabetes mellitus.

It is not possible in this article to describe the clinical pictures presented by these diseases; however, several facts may be of assistance. The hardest livers to palpation are generally produced by carcinoma. It is not well known that a primary or secondary carcinoma of the liver is sometimes accompanied by a quite high fever, may run its entire course without pain, not uncommonly is accompanied by a leukocytosis up to 15,000, and frequently produces no jaundice; however, malignancy is one of the most frequent causes of a long-standing jaundice. An enlarged tongue of liver known as Riedel's lobe may occasionally be found protruding from under the right half of the liver. This may be confused with almost any abdominal tumor on the right side of the abdomen; an alleged Riedel's lobe usually turns out to be nonexistent, most often proving to be a gallbladder mass.

Several factors may prove useful in determining the etiology of a hepatic enlargement. These are:

1. The presence or absence of jaundice.
2. Ascites.
3. The size and shape of the liver.
4. The association with splenic enlargement.

Those diseases with hepatic enlargement which are usually accompanied by little or no obvious jaundice are: cardiac decompensation, liver abscess, leukemia, polyserositis, Banti's syndrome, amyloid disease, and fatty liver. Hepatic enlargement with ascites is most frequently encountered in: malignancy, portal cirrhosis, cardiac decompensation, polyserositis (Pick-Concato's disease), Banti's syndrome, syphilis of the liver, and amyloid disease; it is uncommon in leukemia, Hodgkin's disease, pernicious anemia, and polycythemia. A very large liver is produced usually by primary or secondary tumor (carcinoma, melanoma, angioma), Hodgkin's disease, amyloidosis, and leukemia. The finding of a fair degree of enlargement of both spleen and liver should suggest: leukemia,

subacute bacterial endocarditis, Hodgkin's disease, puerperal sepsis, typhoid fever, portal cirrhosis, septicemia, amyloidosis, melanosarcoma, and possibly pernicious anemia.

The following table is an attempt to enumerate in so far as possible the causes of splenic enlargement.

SPLENIC ENLARGEMENT

I. *Circulatory*

- A. Thrombosis of the portal vein or its branches.
- B. Pericarditic pseudocirrhosis of the liver.
- C. Chronic cardiac decompensation in infants.
- D. Cirrhosis of the liver.

II. *Infections*

- A. Typhoid and paratyphoid fever.
- B. Malaria.
- C. Subacute bacterial endocarditis; malignant endocarditis.
- D. Septicemia.
- E. Undulant fever.
- F. Other acute infections (rheumatic fever, poliomyelitis, influenza, erysipelas, tularemia, relapsing fever, typhus fever, Rocky Mountain spotted fever, pneumonia, Weil's disease).
- G. In children: measles, pneumonia, active rickets, active syphilis, pertussis, otitis media, impetigo, diphtheria, rubella, Still's disease.
- H. Chronic ulcerative colitis.
- I. Tuberculosis and syphilis.
- J. Felty's syndrome.
- K. Abscess of the spleen.
- L. Tropical diseases (kala-azar, Chaga's disease, sleeping sickness, bilharziasis).
- M. Lupus erythematosus (acute or generalized).
- N. Pylephlebitis.
- O. Hepatitis.

III. *Blood Dyscrasias*

- | | |
|------------------------------|---|
| A. Leukemia. | H. Cooley's erythroblastic anemia. |
| B. Hemolytic icterus. | I. von Jaksch's anemia. |
| C. Purpura hemorrhagica. | J. Pernicious anemia. |
| D. Infectious mononucleosis. | K. Banti's syndrome and splenic anemia. |
| E. Hodgkin's disease. | L. Agranulocytic angina. |
| F. Sickle cell anemia. | |
| G. Polycythemia vera. | |

IV. *Metabolic Disturbances*

- | | |
|----------------------------|---------------------|
| A. Gaucher's disease. | E. Amyloidosis. |
| B. Niemann-Pick's disease. | F. Hemochromatosis. |
| C. Xanthomatosis. | G. Lipoidemia. |
| D. Hypercholesterolemia. | H. Toxic goiter. |

V. *Primary Tumors*

- A. Benign (hemangioma, fibroma).
- B. Malignant (sarcoma, lymphosarcoma, reticulum cell sarcoma).
- C. Cysts (hydatid, dermoid, simple, lymphangioma, hemangioma, posttraumatic, hemorrhagic, multiple congenital).

VI. *Unclassified*

- A. Status lymphaticus.
- B. Congenital hydrops (infants).
- C. Giant lymph follicle hyperplasia.
- D. Congenital hematoporphyria.
- E. Albers-Schönberg disease (marble bones).
- F. Movable spleen.
- G. Normal splenic enlargement in infancy.

Splenomegaly should arouse one's curiosity concerning the following points:

- | | |
|---------------------|-------------------------|
| 1. Lymphadenopathy. | 4. Blood picture. |
| 2. Jaundice. | 5. Fever. |
| 3. Ascites. | 6. Hepatic enlargement. |

Diseases associated with splenomegaly which usually present lymph node enlargements are: lymphatic leukemia, Hodgkin's disease, infectious mononucleosis, status lymphat-

icus, lymphosarcoma, Still's disease, some of the acute exanthemata, tuberculosis, septicemia, leukosarcoma, tularemia, syphilis, giant lymph follicle hyperplasia and, very rarely, myelogenous leukemia. Splenic enlargement and ascites should suggest portal cirrhosis, Banti's syndrome, portal thrombosis, amyloid disease, syphilis of the liver, perihepatitis, cardiac decompensation in children, and, occasionally, leukemia, Hodgkin's disease, von Jaksch's anemia and polycythemia. Splenomegaly together with jaundice is seen in hemolytic icterus, Hanot's cirrhosis (and occasionally, 25 per cent of cases, in portal cirrhosis), septicemia, syphilis of the liver, pernicious anemia, yellow fever, malaria, and Weil's disease; jaundice is somewhat uncommon in leukemia, Hodgkin's disease, Banti's syndrome, typhoid fever, and pneumonia. If leukopenia is found, the diseases to be considered will include: pernicious anemia, Banti's syndrome, Gaucher's disease, aleukemic leukemia, agranulocytic angina, typhoid and paratyphoid fevers, malaria, undulant fever, overwhelming infections, measles, kala-azar, and occasionally Hodgkin's disease. If fever accompanies the splenomegaly, one must think of malaria, typhoid and paratyphoid fevers, leukemia (especially the acute form), undulant fever, subacute bacterial endocarditis, Hodgkin's disease, infectious mononucleosis, acute exanthemata, tularemia, typhus fever, Rocky Mountain spotted fever, kala-azar, acute pyelophlebitis, some cases of hepatitis, and occasionally of pernicious and other severe anemias.

Laboratory tests which might be of aid in the differential diagnosis of conditions producing hepatic or splenic enlargement include:

1. Complete blood count: red blood cells, white blood cells, differential, platelets, reticulocytes, search for parasites (malaria, etc.).
2. Examination for macrophages in blood from lobe of ear.
3. Examination for sickling phenomenon.
4. Urinalysis: routine, bilirubin, urobilin, and bile salts.
5. Blood Wassermann reaction.

6. Bleeding time, coagulation time, clot retraction, tourniquet test, volume index.
7. Fragility of the red blood cells.
8. Paul's heterophile antibody test (in diagnosis of infectious mononucleosis, aleukemic leukemia, etc.).
9. Blood agglutination tests: typhoid fever, paratyphoid fever, undulant fever, typhus fever, tularemia.
10. Blood culture.
11. Blood cholesterol, sugar, van den Bergh.
12. Congo red test (possible aid in diagnosis of amyloidosis).
13. Echinococcus complement fixation test.
14. Lymph node or sternal bone marrow biopsy.
15. Gordon test for Hodgkin's disease.
16. Blood viscosity test (in polycythemia).
17. Splenic puncture (of doubtful value).
18. Roentgen examination of the skull and long bones (may be useful in diagnosis of Gaucher's disease, Hodgkin's disease, Cooley's anemia, syphilis, rickets, leukemia, metastatic malignancy, Albers-Schönberg disease, etc.).

A few additional remarks concerning the above tests might prove of value. As regards the differential blood count, the presence of splenic enlargement together with an eosinophilia would suggest echinococcus disease, myelogenous or eosinophilic leukemia, Hodgkin's disease, bilharziasis, scarlet fever, or a postfebrile state. Pepper and Farley³ consider basophilia to be of little diagnostic importance. A lymphocytosis with splenomegaly would call to mind the possibility of infectious mononucleosis, whooping cough, Malta fever, chronic lymphatic leukemia, or possibly toxic goiter or typhoid fever, while an increase in monocytes may be found in subacute bacterial endocarditis, various septicemias, Hodgkin's disease, malaria, monocytic leukemia, etc. A thrombocytopenia may occur in purpura hemorrhagica, acute lymphatic leukemia, kala-azar, pernicious anemia and possibly in some hepatic diseases; thrombocytosis with splenic enlargement has been found in polycythemia, chronic myelogenous leukemia, and Hodgkin's disease. A persisting elevation of reticulocytes should sug-

icus, lymphosarcoma, Still's disease, some of the acute exanthemata, tuberculosis, septicemia, leukosarcoma, tularemia, syphilis, giant lymph follicle hyperplasia and, very rarely, myelogenous leukemia. Splenic enlargement and ascites should suggest portal cirrhosis, Banti's syndrome, portal thrombosis, amyloid disease, syphilis of the liver, perihepatitis, cardiac decompensation in children, and, occasionally, leukemia, Hodgkin's disease, von Jaksch's anemia and polycythemia. Splenomegaly together with jaundice is seen in hemolytic icterus, Hanot's cirrhosis (and occasionally, 25 per cent of cases, in portal cirrhosis), septicemia, syphilis of the liver, pernicious anemia, yellow fever, malaria, and Weil's disease; jaundice is somewhat uncommon in leukemia, Hodgkin's disease, Banti's syndrome, typhoid fever, and pneumonia. 13. Echinococcus complement fixation test.
14. Lymph node or sternal bone marrow biopsy.
15. Gordon test for Hodgkin's disease.
16. Blood viscosity test (in polycythemia).
17. Splenic puncture (of doubtful value).
18. Roentgen examination of the skull and long bones (may be useful in diagnosis of Gaucher's disease, Hodgkin's disease, Cooley's anemia, syphilis, rickets, leukemia, metastatic malignancy, Albers-Schönberg disease, etc.).

A few additional remarks concerning the above tests might prove of value. As regards the differential blood count, the presence of splenic enlargement together with an eosinophilia would suggest echinococcus disease, myelogenous or eosinophilic leukemia, Hodgkin's disease, bilharziasis, scarlet fever, or a postfebrile state. Pepper and Farley³ consider basophilia to be of little diagnostic importance. A lymphocytosis with splenomegaly would call to mind the possibility of infectious mononucleosis, whooping cough, Malta fever, chronic lymphatic leukemia, or possibly toxic goiter or typhoid fever, while an increase in monocytes may be found in subacute bacterial endocarditis, various septicemias, Hodgkin's disease, malaria, monocytic leukemia, etc. A thrombocytopenia may occur in purpura hemorrhagica, acute lymphatic leukemia, kala-azar, pernicious anemia and possibly in some hepatic diseases; thrombocytosis with splenic enlargement has been found in polycythemia, chronic myelogenous leukemia, and Hodgkin's disease. A persisting elevation of reticulocytes should sug-

gest hemolytic ictero-anemia; it is also of diagnostic importance in the remission of primary pernicious anemia. Another diagnostic aid is the search for macrophages in a drop of blood obtained from the lobe of the ear after massage of that part; macrophages may be found under such conditions in typhoid fever, subacute bacterial endocarditis, and possibly in leukemia and malaria. The presence of sickle cells is of course the important hematologic feature of drepanocytosis; these must be searched for in the usual manner by excluding the blood from oxygen for several hours.

The occurrence of urobilin in the urine in the absence of bile pigments and bile salts is a feature of hemolytic icterus. The prolongation of the bleeding time, normal clotting time, poor or absent clot retraction, and positive tourniquet test are well-known points in differentiating purpura hemorrhagica from hemophilia; in the latter, the clotting time is quite prolonged. Demonstration of increased fragility of the red blood cells is essential to the diagnosis of hemolytic icterus.

During the past several years, the introduction of the heterophile antibody test has been of great aid in clinching the diagnosis of infectious mononucleosis. The test is easily performed in any clinical laboratory; agglutination of sheep cells in a dilution of more than 1:16 is pathognomonic of infectious mononucleosis. The only other condition giving a positive test is serum sickness. It has recently been shown that agglutination in only a very low titer is a common occurrence in leukemia.

The value of the Congo red test in the diagnosis of amyloid disease is still open to question; however, a positive reaction is usually indicative of amyloidosis. The Gordon test for Hodgkin's disease (with introduction of macerated lymph node into the brain of a rabbit) is also not fool-proof; recently, positive reactions have been reported in various other diseases.

By careful selection of the appropriate tests in any given case together with a painstaking history and complete physical examination, one should readily be able to arrive at a correct diagnosis.

CLINIC OF DR. EDWARD L. BAUER

JEFFERSON MEDICAL COLLEGE

SCARLET FEVER TODAY

THE laboratory and clinical attack upon scarlet fever that has been so intense since 1925 was stimulated by the claims of the Dicks in 1924 of an etiological factor, the *Streptococcus hemolyticus scarlatinae*, with its toxin and an antitoxin. So much of the laboratory work done on this disease has been presented to the clinician that the clinical aspects have become secondary in his mind. Again he has been confused by the positiveness of diametrically opposite conclusions presented by numerous research workers.

The clinical aspects of the disease can be profitably enumerated since there is no real pathognomonic sign to identify scarlet fever save the possibility of the Schultz-Charlton reaction. This reaction is of value only in the early stage of the rash and only if convalescent serum is used to make the test.

The disease is ushered in after a three- to eight-day incubation period by fever from 101° to 104° F., sore throat about which many children will never complain, and nausea or vomiting which may not occur. Headache, malaise, and chills, or even convulsions in spasmophilic youngsters may or may not occur. Certainly this is not a specific picture of anything. The radial pulse is disproportionately rapid as compared to any degree of temperature that might be present.

Upon examination the tonsils, the pillars, and the soft palate including the uvula will show some degree of injection or erythema. More marked cases will show an intensely reddened throat with punctate red spots over the soft palate.

tecubital spaces lines of red will run across the arm that cannot be blotted out with pressure (Pastia's sign).

An interesting phenomenon concerning the rash is its characteristic but not pathognomonic response to stroking. A white line will appear when the skin is stroked which disappears then reappears and persists for some time. This is called secondary pallor. In fact, constrictions in clothing, such as circular garters, will leave a persistently blanched area. Rumpel-Leede's sign, while not pathognomonic, can be elicited. This is done by applying a fairly tight tourniquet above the elbow causing petechial hemorrhages below. Any degree of itching may occur and an urticaria may accompany the rash.

Leukocytosis occurs in scarlet fever with an eosinophilia. The hemolytic streptococcus can be recovered from the throat and sometimes from the blood stream.

Desquamation may not follow a mild rash. Generally this phenomenon begins in the second or third week and starts on the dry skin in pin-point spots. The loosened serrated edges fusing with other similar areas make irregular patches or strips of peeling skin. Most characteristic is the loss of skin about the fingers and toes, the desquamation going out from the free ends of the nails causing casts of the ends of the fingers that may involve the whole hand, particularly if it is bandaged. The nails may become dry and wrinkled and as they grow out a definite line of demarcation will be seen separating the affected from the healthy nail. It must be remembered however that desquamation is not limited to scarlet fever since branny desquamation may follow measles and the scarlatinal type be reproduced in dermatitis exfoliativa and in other conditions where miliary vesiculation appears.

Scarlet fever may be very mild, so much so that the throat signs may be indifferent, the tongue signs absent, the rash fugacious and its characteristics elusive. The temperature may not go up to any appreciable degree even though the rash may be easily recognized. On the other hand cases of moderate severity will be easily identified by many if not all of the features portrayed. Severe and fulminating cases oc-

The tonsils may be covered with a gray or yellow exudate that when spotty suggests pus.

The tongue will generally be coated. In a few hours the papillae will become swollen and in the beginning particularly on the edge and on the tip they will peep through the coat. Later this occurs over the surface of the tongue giving the appearance of the surface of a raspberry but designated by most American writers as a "strawberry tongue." However in some mild cases of scarlet fever the tongue goes unscathed. As the coating comes off with desquamation the tongue is a deep red and the swollen papillae will stand out giving the appearance of a mulberry. Should this occur it is an aid to diagnosis after the rash has disappeared and before desquamation begins. In marked cases small white spots may be found on the gums that resemble phenol burns.

A general adenopathy occurs and persists, the inguinal glands being among the first that are palpable. In from twelve to seventy-two hours the rash appears although in many cases there is no rash. Only in the severest cases does a typical rash show itself on the face and then on the forehead and under the eyes. Ordinarily the cheeks are flushed with pallor around the alae of the nose and the upper and lower lips. This is the circumoral pallor not always seen in scarlet fever and sometimes seen in other conditions. The rash is first seen beneath the ear and chin lines and beneath the clavicle from which it distributes itself over the remainder of the body with fair rapidity. It may persist from three to seven days before fading out. The rash is essentially diffuse and punctate on an erythematous background. In blondes it is a vivid scarlet and in the more deeply pigmented it becomes duller. In the distinct brunette it has a coppery tinge. It is markedly coppery in the negro. The pores become swollen and stand out and miliaria appear. While the rash is generally evenly distributed in most severe cases, in the milder, tiny areas of healthy skin are scattered over the body. In fact in some few cases large patches of normal skin will be seen between scarlatinal areas. The rash will be found most intense in skin folds. In the an-

tecubital spaces lines of red will run across the arm that cannot be blotted out with pressure (Pastia's sign).

It must be remembered however that desquamation is not limited to scarlet fever since branny desquamation may follow measles and the scarlatinal type be reproduced in dermatitis exfoliativa and in other conditions where miliary vesiculation appears.

Scarlet fever may be very mild, so much so that the throat signs may be indifferent, the tongue signs absent, the rash fugacious and its characteristics elusive. The temperature may not go up to any appreciable degree even though the rash may be easily recognized. On the other hand cases of moderate severity will be easily identified by many if not all of the features portrayed. Severe and fulminating cases oc-

casionally occur. In these cases the throat will be edematous and almost closed. The temperature will reach the higher ranges. The mucous membranes and skin may become hemorrhagic. Upon one occasion I saw five children in one family perish in twelve hours from the onset of their symptoms.

If the streptococcus and its toxin are to be accepted as the cause of scarlet fever then the general run of complications are not complications in the strict sense of the word but variants in the clinical manifestations of the disease. It is true that these manifestations are streptococcic in origin, whether a streptococcic toxin, some other organism with which the streptococcic organism works in symbiosis, or whether they follow in the wake of an allergic phenomenon. Only casual attention is paid to the adenopathy unless the cervical glands become perceptibly enlarged, cause distress, or suppurate as they sometimes do. Cervical adenitis may occur early or late. Suppurative middle ear disease frequently occurs and I have seen it cause much pain and distress even before the rash has put in an appearance. Mastoiditis may occur almost immediately following an otitic infection but generally takes about a week to develop.

While the nasopharynx was not mentioned when the characteristic picture of the throat was described evidence of infection is always present. Sinus involvement occurs which, should it persist, will in the third or fourth week or even earlier be accompanied by a nasal discharge or at least a moisture from which the hemolytic streptococcus can regularly be cultured.

Up to the third week endocarditis, pericarditis, pancarditis, pneumonia, pleurisy, empyema, multiple arthritis, multiple abscesses, appendicitis, peritonitis, osteomyelitis, and meningitis may occur, or any combination thereof. Nephritis occurs more frequently perhaps but occurs ordinarily late. The first evidence of nephritis may be found in the urine, albumin, blood, and casts appearing. Some apathy or irritability may be present. This may be followed rapidly by edema, in other cases by anuria with later edema and unconsciousness. Many

of the more toxic cases with high temperature may be delirious but the meningitis cases present the characteristic physical findings of this condition with a cloudy spinal fluid, increased cell count, and streptococci. The other aforementioned conditions present no picture that diverges from their occurrence without scarlet fever. It is evident that in scarlet fever we have a situation that is developed as a result of the combination of a bacterium and a toxin or allergic element or a toxo-allergen. Yielding to the toxin for a moment the rash, the picture of the tongue, the temperature, and perhaps the vomiting can be regarded as the work of the toxin. The temperature might also be caused by bacterial invasion. Certainly the pathology of the throat is a bacterial manifestation. The other phases commonly referred to as complications are undoubtedly bacterial. I personally do not believe that the nephritis should be excluded from this category in all instances. On the other hand there is much evidence to show that there are allergic characteristics present in the rash and obviously the toxo-allergen theory would have a strong leg to stand upon.

Occasionally there occurs an encephalitis beginning with headache, nausea, vomiting, then stupor, and even unconsciousness. Rigidity of the neck is always present but other signs of meningeal irritation change from hour to hour. Paralysis for some period of time is apt to occur in any extremity. The spinal fluid is clear under pressure with a moderate increase in cells, the polymorphonuclear variety predominating. No organisms are demonstrable. There is a high mortality to this encephalitis but if the patient recovers none of the post-encephalitic sequelae found after epidemic encephalitis occur. It is indeed a picture that parallels in its exactness the virus encephalitis which follows occasionally in the wake of small-pox vaccination, measles, and chicken pox. Here again is evidence for the adherents of the symbiotic group of etiologists.

Before beginning a discussion of the treatment of scarlet fever an appraisal of the investigations into the cause and

asionally occur. In these cases the throat will be edematous and almost closed. The temperature will reach the higher ranges. The mucous membranes and skin may become hemorrhagic. Upon one occasion I saw five children in one family perish in twelve hours from the onset of their symptoms.

If the streptococcus and its toxin are to be accepted as the cause of scarlet fever then the general run of complications are not complications in the strict sense of the word but variants in the clinical manifestations of the disease. It is true that these manifestations are streptococcic in origin, whether a streptococcic toxin, some other organism with which the streptococcic organism works in symbiosis, or whether they follow in the wake of an allergic phenomenon. Only casual attention is paid to the adenopathy unless the cervical glands become perceptibly enlarged, cause distress, or suppurate as they sometimes do. Cervical adenitis may occur early or late. Suppurative middle ear disease frequently occurs and I have seen it cause much pain and distress even before the rash has put in an appearance. Mastoiditis may occur almost immediately following an otitic infection but generally takes about a week to develop.

While the nasopharynx was not mentioned when the characteristic picture of the throat was described evidence of infection is always present. Sinus involvement occurs which, should it persist, will in the third or fourth week or even earlier be accompanied by a nasal discharge or at least a moisture from which the hemolytic streptococcus can regularly be cultured.

Up to the third week endocarditis, pericarditis, pancarditis, pneumonia, pleurisy, empyema, multiple arthritis, multiple abscesses, appendicitis, peritonitis, osteomyelitis, and meningitis may occur, or any combination thereof. Nephritis occurs more frequently perhaps but occurs ordinarily late. The first evidence of nephritis may be found in the urine, albumin, blood, and casts appearing. Some apathy or irritability may be present. This may be followed rapidly by edema, in other cases by anuria with later edema and unconsciousness. Many

of the more toxic cases with high temperature may be delirious but the meningitis cases present the characteristic physical findings of this condition with a cloudy spinal fluid, increased cell count, and streptococci. The other aforementioned conditions present no picture that diverges from their occurrence without scarlet fever. It is evident that in scarlet fever we have a situation that is developed as a result of the combination of a bacterium and a toxin or allergic element or a toxo-allergin. Yielding to the toxin for a moment the rash, the picture of the tongue, the temperature, and perhaps the vomiting can be regarded as the work of the toxin. The temperature might also be caused by bacterial invasion. Certainly the pathology of the throat is a bacterial manifestation. The other phases commonly referred to as complications are undoubtedly bacterial. I personally do not believe that the nephritis should be excluded from this category in all instances. On the other hand there is much evidence to show that there are allergic characteristics present in the rash and obviously the toxo-allergin theory would have a strong leg to stand upon.

Occasionally there occurs an encephalitis beginning with headache, nausea, vomiting, then stupor, and even unconsciousness. Rigidity of the neck is always present but other signs of meningeal irritation change from hour to hour. Paralysis for some period of time is apt to occur in any extremity. The spinal fluid is clear under pressure with a moderate increase in cells, the polymorphonuclear variety predominating. No organisms are demonstrable. There is a high mortality to this encephalitis but if the patient recovers none of the post-encephalitic sequelae found after epidemic encephalitis occur. It is indeed a picture that parallels in its exactness the virus encephalitis which follows occasionally in the wake of small-pox vaccination, measles, and chicken pox. Here again is evidence for the adherents of the symbiotic group of etiologists.

Before beginning a discussion of the treatment of scarlet fever an appraisal of the investigations into the cause and

casionally occur. In these cases the throat will be edematous and almost closed. The temperature will reach the higher ranges. The mucous membranes and skin may become hemorrhagic. Upon one occasion I saw five children in one family perish in twelve hours from the onset of their symptoms.

If the streptococcus and its toxin are to be accepted as the cause of scarlet fever then the general run of complications are not complications in the strict sense of the word but variants in the clinical manifestations of the disease. It is true that these manifestations are streptococcic in origin, whether a streptococcic toxin, some other organism with which the streptococcic organism works in symbiosis, or whether they follow in the wake of an allergic phenomenon. Only casual attention is paid to the adenopathy unless the cervical glands become perceptibly enlarged, cause distress, or suppurate as they sometimes do. Cervical adenitis may occur early or late. Suppurative middle ear disease frequently occurs and I have seen it cause much pain and distress even before the rash has put in an appearance. Mastoiditis may occur almost immediately following an otitic infection but generally takes about a week to develop.

While the nasopharynx was not mentioned when the characteristic picture of the throat was described evidence of infection is always present. Sinus involvement occurs which, should it persist, will in the third or fourth week or even earlier be accompanied by a nasal discharge or at least a moisture from which the hemolytic streptococcus can regularly be cultured.

Up to the third week endocarditis, pericarditis, pancarditis, pneumonia, pleurisy, empyema, multiple arthritis, multiple abscesses, appendicitis, peritonitis, osteomyelitis, and meningitis may occur, or any combination thereof. Nephritis occurs more frequently perhaps but occurs ordinarily late. The first evidence of nephritis may be found in the urine, albumin, blood, and casts appearing. There is a high mortality to this encephalitis but if the patient recovers none of the post-encephalitic sequelae found after epidemic encephalitis occur. It is indeed a picture that parallels in its exactness the virus encephalitis which follows occasionally in the wake of small-pox vaccination, measles, and chicken pox. Here again is evidence for the adherents of the symbiotic group of etiologists.

Before beginning a discussion of the treatment of scarlet fever an appraisal of the investigations into the cause and

serologic aspects should be noted. The controversies that have arisen over the *Streptococcus hemolyticus scarlatinae* which undoubtedly plays a big rôle in scarlet fever, the Dick toxin, and the antitoxins of Dick and Dochez demand scrutiny. The place of convalescent serum must also be established as far as possible.

Ever since the bacterial etiology of scarlet fever have been suspected the streptococcus has been accused. Schleissner, Gabritschewsky, Moser, Dochez, and then the Dicks have claimed a streptococcus and toxin as the cause of scarlet fever. The *Streptococcus hemolyticus scarlatinae* has several strains. The toxins produced by all the strains are not entirely related. Some of the commoner strains are most frequently associated with the mild scarlet fever prevalent in the United States in the last ten years. In the malignant scarlet fever occasionally seen other strains of streptococci are found and the toxins of the former strains do not seem to bear any relation to them.

The Dicks have devised an intracutaneous test for susceptibility to scarlet fever, using the toxin of their *Streptococcus hemolyticus scarlatinae*. Some of the more malignant cases of scarlet fever have occurred in individuals who were Dick test negative. Coste, Zoeller, and di Gröer have found that the test is variable in up to 40 per cent of individuals. It has been demonstrated that a negative test to one strain of toxin does not mean immunity to all strains. I have found positive reactors in 30 per cent of a group of children three years after bona fide attacks of scarlet fever. This is too high a percentage to be a true indication of susceptibility following scarlet fever in the light of clinical experience.

It has been clearly demonstrated that the Dick test does not measure blood antitoxin content. That it depends entirely upon local conditions is the claim of some and upon allergy of others. Ando first separated the toxin into a heat labile and a heat stable toxin. The former has toxic properties, the latter allergic properties.

Recently there has been an increasingly plaintive plea for more accurate standardization in the strength of toxin pro-

duction. The skin test dose of a given toxin seems to vary at present. This coupled with the aforementioned causes of error including the not unimportant variety of strains certainly nullifies the reliability of the test in given individuals.

The active immunization of individuals by the injection of multiple doses of toxin is also advocated by the Dicks. Negative Dick tests follow this effort at immunization. Some individuals have been known to remain negative two years or more. It appears however that this is a vaccinal immunity and if permanency is desired repeated series of injections must be given. Immunity to one strain of toxin does not necessarily confer immunity to all strains.

The reaction to these injections may entail more suffering particularly on the part of older people than scarlet fever itself. An attempt has been made to overcome this by giving smaller doses in greater number than the five prescribed by the Dicks. Since the skin test dose is not a reliable standard this may prove to be a snare or delusion.

The symptoms to be looked for are headache, nausea, vomiting, fever, a scarlatinal rash, sometimes edema and even anasarca, and pretty generally a painful cellulitis at the site of injection.

Evidence of more and more failures to prevent scarlet fever by the use of Dick toxin accumulate while others are positive in their statement that they have never had a failure. This latter is incredible because of the lack of standardization of material and the evident inability to immunize against all strains at one time. The answer seems to lie in the fact that success may attend where only one strain of streptococcus and toxin is present in a given community.

Since immunization with toxin deals exclusively with toxin in a disease in which the organism itself plays a more important part than the toxin the back door remains wide open while the front door is padlocked. This is demonstrated by the fact that cases of scarlet fever sine exanthemata can and do occur in the immunized. In these cases bacterial variants or complications have the same open sesame that they have

in those accompanied by toxemia and rash. With a population highly immunized to the toxin apparently more difficulty will be found in recognizing these cases and they will therefore become more numerous because of a lack of isolation precautions. It will necessitate the careful culturing of all sore throats and the definite identification of the almost omnipresent streptococcus as the Dick streptococcus or another streptococcus. This is by no means easy and certainly not the final word in the solution of this invited public health problem.

Efforts of this nature have already met with signal failure. For example, even with a diagnostic rash to help them O. Bauer and Minkerewitsch in an attempt to detain all scarlet fever carriers, that is, *Streptococcus hemolyticus scarlatinae*, so as to prevent return cases to a contagious disease hospital made no more impression on the number of such unfortunates despite more than 30,000 examinations.

By different technics Dochez and the Dicks both produced an antitoxin. The Dochez antitoxin also carries with it bacteriocidal properties. The Dick antitoxin does not. From the discussion of the clinical picture of scarlet fever a bacteriocidal agent is as important as an antitoxin.

The use of the Dick antitoxin in the treatment of scarlet fever has been followed by a rapid decline in the temperature and an almost sudden release from toxic manifestations. Authorities differ upon the reduction in the number of complications. That they continue to occur is certain and since there is controversy concerning this claim it must be understood that more than simple statistics are necessary before any conclusions can be drawn. To date it must be said that no publications claiming marked reductions in complications have had complete and iron-clad control studies. Otherwise there should be no difference in similarly controlled experiments such as now exist.

Because of the severe reactions to the antitoxin itself and the relatively high proportion of anaphylactic deaths following its use most workers now use the antitoxin simply for se-

vere cases. A more concentrated serum is now available which the producers claim cuts down the protein reactions and they urge its use in the mild as well as severe cases. Its value has yet to be clinically established for not enough work has been done with it to justify all the claims made for it. This fact must be borne in mind particularly in dealing with the milder cases, that if the disease is abruptly terminated there will be far less antibody response and consequently fewer individuals develop immunity to the disease by reason of their attack.

Another unfortunate fact about scarlet fever antitoxin is its lack of standardization. The substitution of antitoxin for convalescent serum in the Schultz-Charlton test led me to try the antitoxin of three commercial houses simultaneously in individual cases in a series of patients of unquestioned scarlet fever. By way of parenthesis, the Schultz-Charlton reaction is the blanching of a rash in a scarlet fever patient about the site of an intracutaneous injection of convalescent scarlet fever serum. In the test there has been substituted antitoxin for the convalescent serum.

I shall present five cases of my series upon whom three blanching tests were attempted simultaneously in each case and all five cases being tested on the same day with the same products. The result can be graphically expressed as follows:

Antitoxins Nos.	1	2	3	
1.	+	—	+	
2.	+	—	+	(+ = blanching)
Patients { 3.	—	—	+	(— = no blanching)
4.	+	—	—	
5.	+	—	—	

These antitoxins by their expiration date had been but recently issued. This series has been duplicated in its inconsistent results by comparison of other scarlet fever antitoxins in other groups of patients. Obviously the experiment relegates the Schultz-Charlton test to pooled convalescent sera if accuracy in diagnosis is sought. It also places the clinical results obtained in the use of some scarlet fever antitoxins in the category of nonspecific protein therapy or in the realm

of the weakness of clinical observations caused by that sometimes human frailty, unbridled enthusiasm. I believe that there is more than a mere leg to stand upon in support of the former premise.

The immunization of contacts with scarlet fever patients is worthy of some discussion. Since so many contacts presumably susceptible fail to contract the disease upon exposure it is not reasonable to presume that immunization either with antitoxin, toxin, or a combination of toxin and antitoxin has protected in isolated instances. In institutions or in hospital wards contact may not have actually occurred as in households for everyone has seen sporadic cases of scarlet fever even in these environs without secondary cases. On the other hand, if these secondary cases actually occur in those upon whom immunization has been attempted then some reason must be sought for the failure.

In 1925, 1926, and 1927 I had five such experiences in three hospitals, that is, secondary cases arising in children who had received prophylactic doses of Dick scarlet fever antitoxin. From then until 1931 I attempted to immunize by a combination of Dick toxin injections following a prophylactic dose of the antitoxin. This proved futile in three instances. Since then I have used neither. Curiously enough, perhaps to establish the vagaries of statistical conclusions, I have had seven sporadic cases in various wards with no secondary cases and no attempt was made at immunization.

In institutions I have attempted to segregate Dick positives and Dick negatives with no appreciable difference in the occurrence of secondary cases in either group. Not that I have not found groups of Dick negatives without secondary cases but there have also occurred Dick negative groups where cases did develop and Dick positive groups where they did not develop. By continuing this over a period of seven years I have come out even.

The immunization of institution children with the Dick toxin has led to an increase in the number of scarlet fever sine exanthemata cases and a number of cases of scarlet fever

with rash. I have experienced no benefit over a long period of time from any form of scarlet fever immunization and in from seven to ten years instead of wholehearted enthusiasm I am overwhelmed with morbid pessimism.

The customary answer is that the technic was faulty, the toxin rendered inert by faulty manipulation, or that it lacked proper standardization. On the first two counts I have adhered strictly to the Dick technic, and on the third I have used nothing but the materials covered by the Dick patents and standardized under their regulations.

To sum up the serologic aspect I confess that I am fascinated by something still elusive in this branch of scarlet fever study. To lay a new and good foundation the patents should be forever waived and the subject returned to the laboratories so that the bacteriologist and serologist will have complete freedom for all manner of study within their ken. With this fresh, unfettered effort will the key be found.

Enough has been said about serology in scarlet fever to justify our lack of faith in Dick antitoxin as a curative agent. True, I repeat, it shortens the acute stage. I have seen the same thing happen when other antitoxins or horse serum have been used. The use of pooled convalescent scarlet fever serum is effectual when given in large doses.

There is undoubtedly the additional element of bacteriocidal potency but this varies with different lots of serum. Should an attempt be made to predetermine and standardize the bacteriocidal potency as well as the antitoxin content after standardization becomes more rigid the product will probably be very expensive and perhaps not generally available. It does seem to be the answer at the moment until an antitoxin more completely developed with antibacteriocidal potency is commercially available. Until then the management of the scarlet fever patient must come under the following regime.

The patient should be isolated and put to bed with the advent of the prodromes. Since this should be routine in all cases of sore throat and fever or undiagnosed acute illness in childhood it is not necessary to wait for definite evidences of

scarlet fever. The isolation should be complete from the very beginning until the patient is released from quarantine. The room should be light and airy with a good heating system. Bathroom facilities for the exclusive use of patient and attendant should be included in the isolated area. Ample quarters for the nurse should be provided since she cannot leave the isolated area until the expiration of quarantine.

Dishes for the patient and nurse should never leave the suite. Garbage should be wrapped and deposited in an otherwise uncontaminated receptacle and removed directly for immediate incineration. All fomites before being sent to a laundry or dry cleaner should be soaked in antiseptics.

Upon termination of quarantine the patient should be given a bath, sent out of the isolated area, and clothed. The nurse then should wipe all walls, floors, and furniture with antiseptic solutions, including mattresses, which should then be exposed to the sun in the open air. The nurse should then take her cleansing bath and don clean clothing outside the restricted area. Toys and books should be destroyed along with the garbage at the last incineration. Lysol, chlorine, and alcohol should be supplied to the nurse freely for use throughout the quarantine. None but the gowned physician should have entrance to the isolated area. If this isolation cannot be attained the patient should be transferred immediately upon making the diagnosis to a contagious disease hospital.

With the patient in bed the diagnosis should be made as soon as possible and the treatment begun. Convalescent serum should be given if available and particularly sought if the case is a severe one. Medicine is usually unimportant. Some physicians use potassium citrate routinely but in excess this may act as a renal irritant. In some cases caffeine is needed as a stimulant and occasionally digitalis is indicated.

The nose should be kept clean with swabs, but oily or aqueous drops and sprays are contraindicated. Their use invariably means an increase in otitic complications. I have never seen any good come from local treatment of the throat and have seen much discomfort accompany and follow its use.

The employment of antiseptics in this procedure is as useless as a cobweb on a levee to hold back a flood. An ice-collar is a source of very welcome comfort for the distressed throat and in cervical adenitis. Be sure that it fits, for the ice-bag will only rest on the chin and chest and by some curious perversion invariably avoid contact with the throat and neck.

The itching can be allayed with carbolated vaselin. Purges and laxatives should never be used since they dehydrate without benefit to the patient. A cleansing enema or colonic irrigation is valuable especially if the temperature is high. Normal salt solution or bicarbonate of soda should be used. Soap enemas should never be given. The diet should include from the very beginning water for its hydrating and diuretic effect. Milk, cooked cereal, and stewed fruit must be given even in the acute stage. Baked potatoes, gelatin and junket, and orange juice within reason can augment this diet. When the fever subsides a full child's diet may be started including meat and eggs. The formerly practiced restriction in diet has no scientific background and clinically the more liberal diet has proved the better course of procedure.

An uncomplicated case should be kept in bed three weeks following the subsidence of the temperature. The urine should be examined two or three times weekly and in complicated cases daily.

The management of complications must be all too frequently surgical. For example, middle ear disease indicates free incision of the drum if this membrane is reddened or glazed. In dealing with the *Streptococcus hemolyticus* one should not wait for bulging since spontaneous rupture of the drum or procrastination in its incision is followed by an unnecessarily high percentage of mastoid infections. If a mastoiditis develops scrupulous cleaning out of all cells and the tip is necessary. If the lateral sinus is involved even if no clot has formed therein it should be removed. In the event that it is not, bacteremia will follow to place the patient in further jeopardy. Mere puncture of the mastoid antrum sim-

ply begs the question and offers another sacrifice to the surgical approach.

In cases of blood stream infection and in cases of severe toxemia frequent small blood transfusions may be given from donors who are comparatively recent scarlet fever convalescents. These act with the same favorable results generally speaking as other types of immunotransfusions. Transfusions in scarlet fever have not been given the emphasis that they justly deserve and many of the severer cases would be better treated with them than with antitoxin.

Arthritis should be treated by immobilization and soothing wet dressings. The surgical complications could be discussed better by a surgeon of experience. Carditis should be managed according to the same indications as in its occurrence in other diseases.

A little more detail in the discussion of renal complications is in order. Vomiting and fever most frequently usher in nephritis. Lethargy or delirium, convulsions or coma, may occur. Anuria may occur and persist for several days. When the child begins to void after such a period large amounts of blood are passed. In other cases the urine will contain much albumin, blood, granular and hyaline casts. Edema is apt to occur in the latter type. The blood pressure and blood chemistry may be undisturbed and if they are disturbed it is only for a brief period of time. Complete recovery does take place in a large number of these cases.

In the last few years there have been many changes in the manner of treatment. Irritants and alkalis had best be avoided. Diuretics should not be employed in the case of anuria or in a case in which the output is very low, at least until there is an obvious trend upward in the urine output. Caffeine and theobromine-sodium salicylate are the best of the diuretics although ammonium chloride should also be regarded with favor. Temporary use of a salt-poor diet is indicated in the presence of edema. It is impossible to give a salt-free diet. Protein should be given in amounts equal to the body demands. Even larger quantities should be given if the

albumin output is very large. It is obvious then that a liberal diet should be used. Fluid intake should not be restricted.

Bleeding may be indicated followed by the transfusion of smaller quantities of blood than were removed. Careful watch must be kept on the acid-base balance and the blood serum protein. Prognostically the renal functional tests have not proved their value, at least in children. In the presence of edema and high blood pressure the intravenous use of magnesium sulphate after the technic of Blackfan and McKhann is effectual.

Hot packs are helpful and the fears expressed in their use by some are groundless. During convalescence and in some cases even before iron tonics are signally helpful. Varying the type of iron frequently seems to add to the value of this mineral.

Until recently little or no attention has been paid to the most frequent of scarlet fever complications, that is, sinusitis. The routine use of nasal douches, sprays, and applications, while not consciously employed for sinus disease, impaired drainage and spread infection rather than abetted the recovery from this persistent complication. Drainage is the important clue to the correction of sinusitis. It can best be accomplished by keeping the nares open and as free as possible of discharges and edematous membranes. Aqueous applications can be used for this purpose and never drops or sprays. Surgical interference is never indicated. Mild suction also aids in the drainage. x-Ray treatments can be used in the persistent or chronic cases.

When desquamation begins it has been the custom to give cocoa butter rubs which are comforting and may aid in the removal of the peeling skin.

A patient presented for release from quarantine to be eligible for contact with his fellows must be examined physically and passed upon on the following counts. There must be no suppurative discharge from any part of the body. There must be no nasal discharge or moisture. Since sinusitis may not show itself before the third week this second postulate can-

not be answered before the fourth week. The hidebound rule of health departments and some others interested in this problem that desquamation must be complete before release from quarantine shall take place has its only working hypothesis in the fact that it measures in many cases the period in which the two preceding postulates are apt to be operative. Since the desquamation is noninfectious and all of the cases of completed desquamation cannot meet the postulates it is obviously an unscientific and inaccurate criterion in the long run. Incidentally two weeks after the completion of desquamation a secondary desquamation of the hands and feet may occur. This is of no significance whatever but complicates the desquamation criterion for release from quarantine.

It is obvious that the discharge from a mastoid, a running ear, or other open wound would deceive no one as a source of "return" cases. The persistent sinusitis with its irregular discharge and its sometimes trivial residual nasal moisture is frequently overlooked or ignored and it is from these cases that the disease is spread even many months after they have been forgotten as potential carriers. For many obvious reasons cultures are impractical as a check on these cases.

Scarlet fever today needs six cardinal points of attack. First, a more comprehensive and intimate knowledge of the clinical aspects of the disease. Second, a more complete isolation of patients. Third, longer periods of confinement to bed and a more liberal view of the management of the patient's diet. Fourth, a more modern and radical approach to the complications, particularly the surgical. Fifth, a more careful and more reasonable approach to the problem of release from quarantine. Sixth, the liberation from the shackles of commercialism of the bacteriological and serological studies necessary for the evolution of a true prophylaxis and specific cure for this disease. It is not one man's God given field for exclusive study and every bacteriologist and serologist should be permitted to study the problems after a return to our original ethics as a basis.

CLINIC OF DR. MARTIN J. SOKOLOFF

JEFFERSON MEDICAL COLLEGE

TREATMENT OF ACUTE PLEURISY IN GENERAL PRACTICE

AN attack of acute pleurisy should always be given careful consideration, since even in its mildest form it may be an indication of serious disease in the underlying lung or elsewhere in the body. Not infrequently such an attack directs attention to pathological change in other organs, which for a time at least might have otherwise escaped detection. Failure to study and manage properly an apparently trivial pleurisy may have an important bearing upon the future health of the patient.

ETIOLOGY

Acute inflammation of the pleura may be either primary or secondary. The primary form is rare. It occasionally results from exposure to cold or from injury to the chest wall. The majority of cases of primary pleurisy are tuberculous and constitute the group formerly classified as idiopathic pleurisy. Funk was of the opinion that the tubercle bacillus is the probable etiological factor in 90 per cent of cases of primary pleurisy. Frequently a case which is apparently primary is in reality secondary to a tuberculous tracheobronchial lymph gland, or to a subpleural tuberculous focus in the lung too small to be recognized either clinically or roentgenographically. Every case of pleurisy for which no definite cause can be found should be regarded as tuberculous in origin. On the other hand, evidence of pleural inflammation is often the first manifestation of pulmonary tuberculosis and it may precede the appearance of frank pulmonary symptoms by many months.

The secondary form is a result of extension of infection from some obvious focus elsewhere. It occurs in association with such pulmonary diseases as tuberculosis, lobar pneumonia, bronchopneumonia, abscess, bronchiectasis, gangrene, infarction, the mycotic infections or neoplasm. Infections may spread to the pleura from inflammatory processes involving the pericardium, the endocardium, the mediastinum or from organs below the diaphragm. It may follow infection in other parts of the body—postoperative septic infections, tonsillitis, or nephritis. Occasionally it occurs in rheumatic fever as part of a general involvement of the serous membranes.

CLINICAL VARIETIES

Acute pleurisy is best classified clinically according to the type of exudate present. It may be fibrinous or plastic (dry), serous or serofibrinous (pleurisy with effusion), suppurative (empyema) or hemorrhagic.

Inflammation of the pleura results first in the formation of a fibrinous exudate. In a typical attack of dry pleurisy the exudate remains fibrinous throughout. If the inflammation progresses, the amount of serous exudate may exceed the amount of fibrin, resulting in serofibrinous pleurisy. The suppurative form is the result of infection by pneumococci, streptococci or other pyogenic organisms, and occasionally by tubercle bacilli. Hemorrhagic pleurisy may occur as a complication of pneumonia but it is usually the result of tuberculosis or of malignant disease of the pleura.

TREATMENT

Since inflammation of the pleura is frequently an accompaniment of, or an extension from, an infectious process elsewhere, it is obvious that a rational system of management of this condition must take into consideration the underlying and associated pathological conditions. Detailed consideration of these factors would lead this discussion too far afield, therefore, I shall limit my remarks to the relief of the pleurisy itself

and briefly summarize the principles to be applied during and after the acute attack.

The management of acute pleurisy is peculiarly a problem for the general practitioner. Since the clinical course is of relatively short duration and alleviation of annoying symptoms can usually be promptly obtained, the majority of patients with acute pleurisy can be satisfactorily treated at home. Hospitalization is required only when thorough study is necessary to determine the exact etiology or when major surgical procedures are indicated.

Dry Pleurisy.—Regardless of the mildness of the symptoms, rest in bed is essential. The patient should remain in bed until after the pain and fever have subsided. The diet should be nourishing and easily digestible. In the beginning a saline purge is indicated and afterward daily evacuation of the bowels should be assured.

The most important consideration in the treatment of dry pleurisy is the relief of pain. If the pain is not severe it may be relieved by counterirritation in the form of mustard plasters or local application of tincture of iodine. Mustard plasters are ideal counterirritants. They can be readily prepared, their strength can be regulated to suit the age of the patient and sensitivity of the skin, and the degree of rubefaction produced by them can be easily controlled. They are especially useful in the mild recurring attacks of pleurisy in tuberculous patients.

If the pain is severe, immobilization of the affected side by adhesive plaster usually affords immediate relief. With the chest in the position of full expiration, strips of plaster about 2½ inches wide are applied. The strips are started across the vertebral column, drawn tightly around the affected side and attached just beyond the midline in front. They should be placed at right angles to the vertebral column and not follow the line of the ribs. Each strip should overlap the preceding one by one third its width. If the pain is localized in the lower part of the chest two or three strips will suffice, but if it is widely distributed, the strips should be applied up

to the axilla. Hairy chests should be shaved before the adhesive plaster is applied in order to facilitate its removal. In the female, the breast should be drawn up and a small pad of cotton placed over the nipple before being covered by the adhesive. If the pain is in the upper part of the chest several strips may be attached to the anterior chest wall at the level of the fourth rib and pulled firmly over the shoulder to below the spine of the scapula. The plaster should be removed after four or five days or sooner if the patient complains of itching.

If the strapping does not afford complete relief from pain, codeine sulphate may be given by mouth in $\frac{1}{4}$ -grain doses every three or four hours. The codeine will also control the annoying cough which is sometimes present. Acetylsalicylic acid, 5 grains, may be combined with codeine in capsule form. In severe pain not relieved by the above measures, morphine, $\frac{1}{4}$ grain, may be administered hypodermically, but this is rarely necessary.

Pleurisy with Effusion.—The fundamental rules regarding rest, diet, elimination and pain described for dry pleurisy are to be followed. Rest in bed should be continued until the fluid has entirely disappeared. Pain is not an important consideration in this variety of pleurisy, as it is present only for a short time at the onset and disappears with the development of the fluid.

The most important factor in serofibrinous pleurisy is the management of the fluid. It must be borne in mind that spontaneous absorption of pleural effusion occurs frequently. Nearly all small effusions, and occasionally large ones, disappear if the patient is at rest in bed. If the general condition is good and if dyspnea and fever are not causing concern, it is advisable to continue bed rest for several weeks in the hope that spontaneous absorption will take place.

A salt-free diet, restriction of fluid intake, the application of cups or fly blisters to the chest wall, and the induction of profuse diuresis by means of such drugs as theobromine sodium salicylate and salyrgan, have been advised to increase

absorption of the fluid. These measures are of doubtful value, and, as a rule, only add to the discomfort of the patient.

If the effusion occurs as a complication of rheumatic fever salicylates are beneficial. Sodium salicylate, 20 grains, combined with an equal quantity of sodium bicarbonate may be given every three or four hours.

Calcium is believed by some to favor the absorption of fluid from the pleural cavity. Calcium chloride (20 grains) or calcium gluconate (60 grains) may be given orally every three or four hours, or 5 or 10 cc. of a 10 per cent solution of calcium gluconate may be given intravenously once or twice daily for four days. If given intravenously, calcium should be injected slowly in order to avoid unpleasant subjective sensations. According to Kreich, effusions occurring as complications of pneumothorax therapy in tuberculosis may disappear following the intrapleural injection of calcium. He advises the removal of 5 or 10 cc. of the pleural fluid and its replacement by a similar amount of 10 per cent solution of calcium gluconate once daily for three or four days.

Thoracentesis or aspiration of fluid from the pleural cavity is indicated as follows:

1. For diagnostic purposes (15 to 20 cc. is sufficient for cytodiagnosis, culture and animal inoculation).
2. If the effusion is causing cyanosis or dyspnea.
3. If there is continued fever.
4. If the effusion is increasing in amount.
5. If there is no absorption after a reasonable period of conservative treatment (bed rest).
6. If tubercle bacilli are present in the sputum and the opposite lung appears normal the effusion should be converted into a therapeutic pneumothorax by gradual replacement with air.

While aspiration of fluid from the pleural cavity is a relatively safe procedure, it is not entirely without danger. The fluid must be removed slowly and not more than 1500 cc. should be withdrawn at one time. Rapid diminution in intrapleural pressure may cause sudden shifting of mediastinal

structures with immediate production of alarming symptoms. The complications of thoracentesis are: (1) severe cough, (2) pain, (3) fainting or dizziness, (4) dyspnea, (5) hemoptysis, (6) pulmonary edema and (7) pleural shock resulting in sudden death. If the patient coughs or complains of pain or dizziness during thoracentesis, the operation should be stopped and no other attempts to remove the fluid should be made until at least twenty-four hours have elapsed.

Technic of Thoracentesis.—The patient should lie on the sound side, close to the edge of the bed, with the arm extended over the head. A firm pillow should be placed under the lower part of the chest to arch the affected side thus increasing the width of the intercostal spaces. The operation must be performed under rigidly aseptic precautions. Puncture should be made through the sixth or seventh interspace, usually just in front of the angle of the scapula. The skin in the area selected is painted with tincture of iodine and the excess iodine removed with alcohol. Local anesthesia is necessary and a 2 per cent procaine solution may be used for this purpose, being injected intracutaneously by means of a fine hypodermic needle until a wheal is formed. The needle should then be withdrawn and a 20-gauge 3-inch needle attached to the syringe. This needle is inserted through the bleb and is gently forced into the deeper tissues as constant pressure is made on the piston of the syringe. Puncture should be made close to the upper border of the rib in order to avoid injury to the intercostal vessels. The parietal pleura should be carefully injected because of its high degree of sensitivity. Sudden lessening of resistance will indicate that the parietal pleura has been penetrated and that the needle is in the pleural cavity. If traction is made on the piston, the fluid can be seen to rise in the glass tip and enter the barrel of the syringe. The needle should never be introduced up to the hilt for if it breaks at this point it will be difficult to recover. If the fluid is required for diagnostic purposes only, the small syringe is replaced by a 20 cc. syringe and the required amount of fluid is withdrawn and transferred to a sterile container.

If aspiration is to be performed one of the following methods is used:

1. *Negative Pressure Aspiration*.—The Potain aspirator is the apparatus most frequently used in this procedure. It consists of a bottle fitted with a two-way stopcock. One opening is connected to a vacuum hand pump by a piece of rubber tubing. The other opening is connected to the needle in the chest by a similar piece of tubing. The air is removed from the bottle by means of the pump and the valve between the bottle and the pump is closed. The other valve is then opened and the fluid flows from the pleural cavity into the bottle because of the difference in pressure. This apparatus should always be tested before using to make sure there is no leak in the valve and no block in the tubing.

2. *Siphonage*.—This is a simple method of removing fluid from the pleural cavity but it should be used only if an aspirator is not available. A rubber tube is attached to the needle in the chest and the free end is put into a basin half filled with water, which is placed on the floor. A cough will start the flow of fluid through the tube and it will be drawn into the basin by siphonage.

3. *Air Replacement*.—This is indicated in cases of pulmonary tuberculosis where continued collapse of the lung is desired. The effusion is converted into an artificial pneumothorax by removing the fluid and replacing it with air. Two punctures should be made for this purpose, one above the other, in different interspaces. The fluid should be removed through the lower puncture and air introduced through the upper. A pneumothorax apparatus should be used for the introduction of the air so that the amount of air entering the pleural cavity can be measured and the pressure controlled. The fluid should not be entirely removed at one operation, the replacement being accomplished gradually.

After aspiration has been completed the needle should be withdrawn and the puncture point sealed with cotton soaked in collodion or held in place by adhesive.

Empyema.—The presence of an acute purulent pleural

structures with immediate production of alarming symptoms. The complications of thoracentesis are: (1) severe cough, (2) pain, (3) fainting or dizziness, (4) dyspnea, (5) hemoptysis, (6) pulmonary edema and (7) pleural shock resulting in sudden death. If the patient coughs or complains of pain or dizziness during thoracentesis, the operation should be stopped and no other attempts to remove the fluid should be made until at least twenty-four hours have elapsed.

Technic of Thoracentesis.—The patient should lie on the sound side, close to the edge of the bed, with the arm extended over the head. A firm pillow should be placed under the lower part of the chest to arch the affected side thus increasing the width of the intercostal spaces. The operation must be performed under rigidly aseptic precautions. Puncture should be made through the sixth or seventh interspace, usually just in front of the angle of the scapula. The skin in the area selected is painted with tincture of iodine and the excess iodine removed with alcohol. Local anesthesia is necessary and a 2 per cent procaine solution may be used for this purpose, being injected intracutaneously by means of a fine hypodermic needle until a wheal is formed. The needle should then be withdrawn and a 20-gauge 3-inch needle attached to the syringe. This needle is inserted through the bleb and is gently forced into the deeper tissues as constant pressure is made on the piston of the syringe. Puncture should be made close to the upper border of the rib in order to avoid injury to the intercostal vessels. The parietal pleura should be carefully injected because of its high degree of sensitivity. Sudden lessening of resistance will indicate that the parietal pleura has been penetrated and that the needle is in the pleural cavity. If traction is made on the piston, the fluid can be seen to rise in the glass tip and enter the barrel of the syringe. The needle should never be introduced up to the hilt for if it breaks at this point it will be difficult to recover. If the fluid is required for diagnostic purposes only, the small syringe is replaced by a 20 cc. syringe and the required amount of fluid is withdrawn and transferred to a sterile container.

If aspiration is to be performed one of the following methods is used:

1. *Negative Pressure Aspiration*.—The Potain aspirator is the apparatus most frequently used in this procedure. It consists of a bottle fitted with a two-way stopcock. One opening is connected to a vacuum hand pump by a piece of rubber tubing. The other opening is connected to the needle in the chest by a similar piece of tubing. The air is removed from the bottle by means of the pump and the valve between the bottle and the pump is closed. The other valve is then opened and the fluid flows from the pleural cavity into the bottle because of the difference in pressure. This apparatus should always be tested before using to make sure there is no leak in the valve and no block in the tubing.

2. *Siphonage*.—This is a simple method of removing fluid from the pleural cavity but it should be used only if an aspirator is not available. A rubber tube is attached to the needle in the chest and the free end is put into a basin half filled with water, which is placed on the floor. A cough will start the flow of fluid through the tube and it will be drawn into the basin by siphonage.

3. *Air Replacement*.—This is indicated in cases of pulmonary tuberculosis where continued collapse of the lung is desired. The effusion is converted into an artificial pneumothorax by removing the fluid and replacing it with air. Two punctures should be made for this purpose, one above the other, in different interspaces. The fluid should be removed through the lower puncture and air introduced through the upper. A pneumothorax apparatus should be used for the introduction of the air so that the amount of air entering the pleural cavity can be measured and the pressure controlled. The fluid should not be entirely removed at one operation, the replacement being accomplished gradually.

After aspiration has been completed the needle should be withdrawn and the puncture point sealed with cotton soaked in collodion or held in place by adhesive.

Empyema.—The presence of an acute purulent pleural

effusion is an indication for immediate drainage of the pleural cavity. In rare instances, however, repeated aspiration of the exudate may cause reabsorption. Resolution of purulent exudates has been noted by Major following the injection of gentian violet into the pleural cavity. He recommends aspiration of the fluid and the introduction of 100 cc. of a 1:5000 aqueous solution of gentian violet. In the majority of cases intercostal incision or rib resection and drainage is necessary.

Hemorrhagic Pleurisy.—In the absence of infection hemorrhagic pleural effusions will usually be absorbed spontaneously. Massive effusions, or those which are causing fever or dyspnea, should be aspirated. In the presence of infection, prompt surgical treatment to establish free drainage is indicated.

AFTER-TREATMENT

Because acute inflammation of the pleura is so often the result of tuberculous infection, the after-treatment, in many instances, is more important than the treatment of the acute attack. All patients who have had more than one attack of dry pleurisy, or who have developed pleural effusion for which no cause can be found, should be considered tuberculous. A routine method of living, with special reference to rest, diet and fresh air should be outlined and the importance of adhering to this régime carefully explained. If the general condition is unfavorable or convalescence is slow, sanatorium treatment is advisable. Following an acute attack of pleurisy the patient should be reexamined at regular intervals, over a period of several years, for evidence of pulmonary disease. After empyema or hemorrhagic pleurisy the ordinary procedures advised during convalescence from any severe infection must be followed.

CUMULATIVE INDEX

- ABDOMINAL diseases causing fever in children, *July*, 21
 Abortion, diagnostic mistakes, *July*, 76
 habitual, *July*, 81, 93
 Abscess, abdominal, in children, *July*, 26
 mediastinal, in children, *July*, 18
 of brain in children, *July*, 43
 of kidney, multiple, in children, *July*, 33
 of lung, multiple, in children, *July*, 18
 perinephric, in children, *July*, 33
 retropharyngeal, in children, *July*, 13
 subphrenic, in children, *July*, 26
 Adenoids, infected, fever due to, *July*, 10
 Alternation of heart, *July*, 188
 Amebic dysentery in children, *July*, 24
 Anemia, sickle cell, *July*, 55
 Appendicitis, acute, in aged, *July*, 133
 in children, fever in, *July*, 25
 Arcus senilis, *July*, 128

ENDOCRINE SYMPOSIUM

THE following clinics are included in this Symposium:

Cyril M. MacBryde: BORDERLINE ENDOCRINE DISTURBANCES.

Max Deutch: THE DIAGNOSIS AND TREATMENT OF ENDOCRINE INFANTILISM.

Harold A. Bulger: ENDOCRINE OBESITY.

David P. Barr and Kurt Mansbacher: THE TREATMENT OF PITUITARY INSUFFICIENCY AND PITUITARY HYPERFUNCTION.

Louis F. Aitkin: DIAGNOSIS AND TREATMENT OF HYPERINSULINISM.

CLINIC OF DR. CYRIL M. MACBRYDE

FROM THE DEPARTMENT OF MEDICINE, WASHINGTON UNIVERSITY SCHOOL OF MEDICINE AND THE BARNES HOSPITAL

BORDERLINE ENDOCRINE DISTURBANCES

THE recognition of typical examples of endocrine disease should not be difficult. The classical signs of fully developed myxedema, acromegaly or Addison's disease, for example, are so impressive that their diagnosis is almost inescapable. It is not widely appreciated, however, that the milder grades of endocrine dysfunction probably occur much more frequently than the "textbook pictures," and that the presenting symptoms may be so varied or obscure as to be quite misleading. Because of their much greater frequency, and the more satisfactory response to treatment which may be expected in these less severe or "borderline" cases, their recognition is perhaps more important than the diagnosis of the fully developed, frequently hopeless glandular diseases.

HYPOTHYROIDISM

Many patients are seen who have metabolic rates well below the average normal, yet show no signs of clinical hypothyroidism. In the absence of symptoms or signs in such individuals, who otherwise seem perfectly healthy, thyroid medication is not indicated. Further observation is advisable, since definite indications are often slow in development. It is well in such instances to remember that our conception of the normal basal metabolic rate is based upon averages of supposedly normal persons and cannot be too strictly interpreted in its individual application. It must also be kept in

mind that undernutrition alone may cause a marked lowering of the metabolic rate. Restoration of adequate food intake is often accompanied by rapid weight gain and return of oxygen consumption to normal.

Definite hypothyroidism may, however, be manifested in more or less advanced degree without evident myxedema. Symptoms occur in great variety and may include excessive fatigue, sensitivity to cold, nervousness, irritability, constipation, vague muscular or rheumatoid pains, amenorrhea, menorrhagia or metrorrhagia, dryness and roughness of the skin, thinning and dryness of the hair, pallor and dyspnea. Mental sluggishness is by no means the rule, as nervousness and irritability may be major complaints. Mental disturbances may be evidenced by a true depression. Retarded healing of skin or mucous membrane lesions may be seen. Hypothyroid patients frequently are moderately obese, but may be thin. Anemia is present in most of the cases that have persisted for some time. The condition is frequently seen in women going through the menopause, although it may occur in young girls or older women. As is true of other thyroid disorders and typical myxedema, men are affected less frequently than women.

The following reports will illustrate the importance of discovering a lowered metabolism in such atypical cases:

Ulcer of Nasal Septum and Hypothyroidism.—G. H., a woman of forty-nine, had suffered with a painful ulcer of the nasal septum for seven years. She had been steadily gaining weight for several years and was moderately obese. Menses were regular. There was some fatigue and dryness but no thickening of the skin. Mentally she was quite active. Her pulse rate was 66, blood pressure 130 systolic, 70 diastolic. Blood cholesterol was 240, basal metabolism minus 22 per cent. Shortly after the institution of thyroid medication improvement in the ulcer was noted. In six months the ulcer had healed completely.

Hypothyroidism Simulating Hyperthyroidism.—J. D., a woman of thirty-four, complained of nervousness, palpi-

tation and a swelling in her neck, all present for some years. but becoming increasingly annoying. She had had scanty menses for five years, lasting only one day. Emotional upset, weeping spells and severe depression to the point of suggesting suicide had been increasingly evident. She was moderately obese, the skin was flushed and moist, the palpebral fissures were wide and there was slight exophthalmos. The thyroid was moderately and diffusely enlarged. There was slight tremor of the fingers. The blood pressure was 110 systolic, 70 diastolic, and the pulse rate 80. The first impression was that she had mild hyperthyroidism, but the normal pulse and normal pulse pressure made this seem unlikely. The basal metabolism was minus 16 per cent. Appropriate small doses of desiccated thyroid caused a disappearance of the depressed state, lessened the irritability, and restored the menses to normal in duration and amount.

Irritability, Enuresis, Obesity and Hypothyroidism.

—Z. F., a girl of fourteen, complained of easy fatigue, laziness, enuresis, irritability and a very rapid gain in weight. She was somewhat behind girls of her own age in school. The skin was normal. Menses were regular. Pulse was 84, blood pressure 112 systolic, 78 diastolic. Basal metabolism was minus 20 per cent. Within three months after restoration of the basal metabolism to normal, all symptoms were relieved and rapid improvement was noted in her school work. Control of her weight continued to prove difficult, however, and she is still moderately obese. She now is quite energetic and has an equable disposition.

Heart Block, Fainting Attacks and Hypothyroidism.

—Blackford and Willius¹ and others have reported beneficial effects from thyroid medication in Adams-Stokes syndrome and complete heart block. In myxedema the interval between auricular and ventricular contractions may be much prolonged, and the pulse very slow, but true heart block appears to be very rare.

L. M., a man aged forty-four, had weakness for a year, constipation, and frequent occipital headaches. One day

mind that undernutrition alone may cause a marked lowering of the metabolic rate. Restoration of adequate food intake is often accompanied by rapid weight gain and return of oxygen consumption to normal.

Definite hypothyroidism may, however, be manifested in more or less advanced degree without evident myxedema. Symptoms occur in great variety and may include excessive fatigue, sensitivity to cold, nervousness, irritability, constipation, vague muscular or rheumatoid pains, amenorrhea, menorrhagia or metrorrhagia, dryness and roughness of the skin, thinning and dryness of the hair, pallor and dyspnea. Mental sluggishness is by no means the rule, as nervousness and irritability may be major complaints. Mental disturbances may be evidenced by a true depression. Retarded healing of skin or mucous membrane lesions may be seen. Hypothyroid patients frequently are moderately obese, but may be thin. Anemia is present in most of the cases that have persisted for some time. The condition is frequently seen in women going through the menopause, although it may occur in young girls or older women. As is true of other thyroid disorders and typical myxedema, men are affected less frequently than women.

The following reports will illustrate the importance of discovering a lowered metabolism in such atypical cases:

Hypothyroidism Simulating Hyperthyroidism.—J. D., a woman of thirty-four, complained of nervousness, palpi-

tation and a swelling in her neck, all present for some years. but becoming increasingly annoying. She had had scanty menses for five years, lasting only one day. Emotional upset, weeping spells and severe depression to the point of suggesting suicide had been increasingly evident. She was moderately obese, the skin was flushed and moist, the palpebral fissures were wide and there was slight exophthalmos. The thyroid was moderately and diffusely enlarged. There was slight tremor of the fingers. The blood pressure was 110 systolic, 70 diastolic, and the pulse rate 80. The first impression was that she had mild hyperthyroidism, but the normal pulse and normal pulse pressure made this seem unlikely. The basal metabolism was minus 16 per cent. Appropriate small doses of desiccated thyroid caused a disappearance of the depressed state, lessened the irritability, and restored the menses to normal in duration and amount.

Irritability, Enuresis, Obesity and Hypothyroidism.

—Z. F., a girl of fourteen, complained of easy fatigue, laziness, enuresis, irritability and a very rapid gain in weight. She was somewhat behind girls of her own age in school. The skin was normal. Menses were regular. Pulse was 84, blood pressure 112 systolic, 78 diastolic. Basal metabolism was minus 20 per cent. Within three months after restoration of the basal metabolism to normal, all symptoms were relieved and rapid improvement was noted in her school work. Control of her weight continued to prove difficult, however, and she is still moderately obese. She now is quite energetic and has an equable disposition.

Heart Block, Fainting Attacks and Hypothyroidism.

—Blackford and Willis¹ and others have reported beneficial effects from thyroid medication in Adams-Stokes syndrome and complete heart block. In myxedema the interval between auricular and ventricular contractions may be much prolonged, and the pulse very slow, but true heart block appears to be very rare.

L. M., a man aged forty-four, had weakness for a year, constipation, and frequent occipital headaches. One day

while attending church he lost consciousness for some minutes. There were no convulsive movements and upon regaining consciousness he was able to walk home. Similar attacks occurred at irregular intervals over a period of several months. He was obese and there were numerous fairly large lipomata on arms, back, abdomen and legs. The heart was not enlarged and there were no murmurs. Blood pressure was 105 systolic, 80 diastolic. The pulse rate was 36. The skin was not dry or thickened. Basal metabolism tests were minus 32 and minus 37 per cent. The electrocardiograms showed slurring of the QRS complexes, rates 36 to 54, and the P-R interval was 24 seconds. This was interpreted as evidence of delayed auriculoventricular conduction, possibly partial heart block. With 3 grains of thyroid per day the metabolism rose to normal, the pulse ranged from 64 to 78, the P-R interval was shortened, the blood pressure rose to 130 systolic, 70 diastolic, and there was no recurrence of the fainting attacks.

The relief of the attacks following the restoration of the metabolism to normal suggested that the syncope might have been associated with the low blood pressure and prolonged P-R interval resulting from the hypothyroidism.

Anemia, Constipation, Muscular Pains, Cramps and Hypothyroidism.—D. R., a woman aged forty-nine, had noticed easy fatigue for four months. Constipation had been severe and had been controlled only by generous use of commercial saline cathartics. Her menses had stopped two years ago. Stiffness and aching in both hips and shoulders and in the neck had been present intermittently. There were frequent cramps in the bottom of the left foot. She had frequent colds. She was thin, somewhat pale, and appeared weak and chronically ill. The skin was dry but not thickened. The pulse was 64, blood pressure 115 systolic, 70 diastolic. She was mentally and physically hyperactive and irritable. The red blood cell count was 3,430,000, hemoglobin 67 per cent.

The basal metabolism was minus 28 per cent. Restoration of the metabolic level to normal resulted in complete relief of

the muscular pains and cramps and the constipation. The blood count is improving and she is less nervous and irritable.

Not one of the patients here described had the usual "typical" signs of marked hypothyroidism. The mental sluggishness, thickened skin, hair loss, sleepiness, changed facial appearance, hoarse voice, marked weight gain may be absent in many patients. Instead of these symptoms we find that muscular pains, enuresis, nervous irritability, anemia, constipation, or changes in the electrocardiogram may serve to direct our attention toward the possibility of hypothyroidism.

Differential Diagnosis.—Perhaps the most frequent pitfall is the tendency to class many of these patients as "menopausal syndrome" or "menopausal neurosis." The connection with the menopause is indeed clear in many instances but thyroid medication is frequently indicated instead of estrogenic substance, or psychotherapy. Obscure muscular aches and pains especially if associated with a dry skin or constipation may suggest the true diagnosis in an unresponsive case of "arthritis," "neuralgia" or "rheumatism." A supposed spastic or atonic colitis may respond dramatically to appropriate thyroid medication. Stubborn anemias responding poorly to iron may show marked improvement if a low metabolism is brought to normal. The blood may return to normal in the severe anemias with thyroid alone but the use of iron and liver extract will usually give a more rapid response.

Clinically patients with pernicious anemia or myxedema may closely resemble each other. Both may have easy fatigue, dyspnea upon exertion, edema, sensitivity to cold, pains or paresthesia, and yellowish pallor. Careful study of the blood changes will often serve to distinguish the two except in the infrequent patients in whom the diseases coexist.² The smooth, atrophic, sore tongue of pernicious anemia may be found in contrast to the large, thickened tongue of myxedema. Achlorhydria is characteristic of pernicious anemia, but also is found frequently in myxedema. The basal metabolism in uncomplicated pernicious anemia is not usually depressed and may be elevated.

Stubborn anemias responding poorly to iron may show marked improvement if a low metabolism is brought to normal. The blood may return to normal in the severe anemias with thyroid alone but the use of iron and liver extract will usually give a more rapid response.

Clinically patients with pernicious anemia or myxedema may closely resemble each other. Both may have easy fatigue, dyspnea upon exertion, edema, sensitivity to cold, pains, paresthesia, and yellowish pallor. Careful study of the blood changes will often serve to distinguish the two except in the infrequent patients in whom the diseases coexist.² The smooth, atrophic, sore tongue of pernicious anemia may be found in contrast to the large, thickened tongue of myxedema. Achlorhydria is characteristic of pernicious anemia, but achlorhydria is found frequently in myxedema. The basal metabolism in uncomplicated pernicious anemia is not usually depressed and may be elevated.

Patients with obesity are nearly always suspected of hypothyroidism, but the basal metabolic rate in my experience is more often normal or elevated. The use of thyroid preparations in obesity without hypothyroidism may be dangerous and is ordinarily unjustifiable. Certain dermatological entities such as atopic dermatitis, ichthyosis, scleroderma, and senile eczema may improve with thyroid medication. In most instances there is no definite evidence of hypothyroidism in such cases but the accelerated skin metabolism may produce the beneficial results. Low metabolism with a marked tolerance for thyroid is seen in nephrosis, as described by Epstein.³ Diuresis, with lessened edema and general improvement may result in such patients when thyroid is given, but there is probably no true hypothyroidism. Patients with chronic nephritis often closely resemble those with myxedema since both may have pale, puffy faces and bodies, anemia, weakness, and be stuporous or disoriented.

In doubtful borderline hypothyroid cases one should remember that the patient's first metabolism test may give a figure higher than his true basal, and it is wise to repeat such tests. Thyroid conditions are fluctuant, and variable in severity so that metabolism tests repeated at intervals are very helpful. Blood cholesterol determinations over 200 mg. per cent support the impression of a lowered metabolism. Lastly, and of considerable importance: do not discontinue therapy and change the diagnosis if definite results are not apparent in one or two weeks. It may take several weeks or a month to raise the metabolism to normal, and some of the symptoms and signs may not disappear until the metabolism has been normal for some time.

HYPERTHYROIDISM

Two classes of patients offer considerable difficulty in the differential diagnosis of hyperthyroidism. One group have an elevated metabolic rate with few or no hyperthyroid symptoms or signs, the other group have striking signs or symptoms with metabolic rates within the normal range. Condi-

tions such as fever, leukemia, pernicious anemia and cardiac decompensation may cause elevated metabolic rates. All the so-called "classic" signs may be present in the absence of true thyrotoxicosis. Exophthalmos may be congenital, the tachycardia may be caused by infection, anemia or heart disease, and the tremors may be a pure nervous manifestation. Nodular or diffuse thyroid enlargement may be present without hypersecretion. The flushed face and tachycardia of mitral stenosis or vascular hypertension are often misleading. The weight loss, tachycardia, gastro-intestinal irritability and nervousness of early pulmonary tuberculosis may cause errors in diagnosis.

Among the nonthyroid conditions with symptoms suggesting thyrotoxicosis, neurocirculatory asthenia is most commonly seen. Hyperthyroid individuals and patients suffering from effort syndrome both complain of palpitation, dyspnea or excess fatigue on exertion, irritability, tremor and emotional imbalance. Both may be hyperkinetic, and suffer from insomnia, phobias and apprehension. The following case report indicates how such patients may be distinguished from those with true hyperthyroidism.

L. M., a married woman of twenty-three, became irritable and apprehensive and complained of rapid heart beat shortly following the birth of her first child. She had had a small diffuse goiter, first noted at about the age of fifteen. At that time she had suffered from similar nervous symptoms, and had been given a medicine she believed to contain iodine, following which the nervous symptoms improved and the goiter became smaller. In the year following the birth of her child she lost 15 pounds in weight. Her face and neck were flushed, there was slight exophthalmos, the thyroid was slightly but diffusely enlarged and there was a slight tremor of the fingers. The pulse ranged from 80 to 115 and the blood pressure was 110 systolic, 65 diastolic. A basal metabolism before hospital entry was reported as plus 16 per cent. Basal metabolism tests after entering the hospital were minus 2, minus 7, and minus 3 per cent. Creatine and creatinine excretion upon

a controlled diet were within normal limits. Blood cholesterol determinations ranged between 125 and 170 mg. per cent. Lugol's solution was administered as a diagnostic test as described by Means.⁴ The basal metabolism did not fall, being plus 1 and minus 1 per cent after twelve days, and the creatine and creatinine excretion was unchanged.

True hyperthyroidism may occur in the presence of a metabolic rate falling within the usually accepted normal range of plus 10 to minus 10 per cent. The symptoms and physical signs in such cases are usually borderline in character, but may be quite definite. As contrasted with patients who have neurocirculatory asthenia, the pulse rate at rest remains high, the pulse pressure is increased and there is a fall in the basal metabolism after taking iodine. It must be concluded that the normal basal metabolism in such patients is below or at the lower limit of the commonly accepted normal range. If an individual's normal rate were minus 15 per cent, a figure of plus 10 would represent a 25 per cent elevation. It should be again emphasized that thyroid function is fluctuant and that a truly toxic patient seen during a remission may have a normal rate. Thyrotoxicosis without elevated metabolism has been called the "larval" type or "form fruste." Clute,⁵ Troell,⁶ Plummer⁷ and others have described such patients. Gordon and Graham⁸ concluded that it occurs more commonly with nodular goiter (54 of their 71 cases). Cardiac insufficiency, probably the result of a prolonged mild hyperthyroidism, was found frequently in such patients over forty years old with nodular goiter. Subtotal thyroidectomy resulted in clinical cures in 53 per cent of the patients with diffuse goiter, and in 67 per cent of those with nodular goiter. The metabolic rates on the average decreased very little, but pulse rates were slower and pulse pressures diminished.

The following case illustrates the fluctuant nature and diagnostic characteristics of such borderline cases:

Hyperthyroidism with Normal Metabolic Rate.—G. S., a man of twenty-seven, had complained of goiter, nervousness, palpitation, and excess perspiration, for several years.

The thyroid had gradually diffusely enlarged. Marked variations were noted from time to time in its size. His skin was flushed and warm; there was definite tremor of the hands. A soft bruit could be heard over the gland. The pulse rate was 100, the blood pressure 150 systolic, 90 diastolic. During two years' observation there were moderate variations in the severity of symptoms and repeated basal metabolic rates averaged plus 6 per cent. At one time iodine was given and the rate fell to minus 1 per cent and the pulse to 84. At another time after three control determinations varying from plus 10 to plus 6, rest and phenobarbital resulted in a fall to minus 6 per cent with a pulse of 80 and blood pressure 125 systolic, 70 diastolic. He is still under observation and thyroidectomy will probably be advised.

ADRENAL INSUFFICIENCY

Addison's disease in its fully developed form is fortunately relatively rare. It is not uncommon, however, to encounter patients with less severe symptoms strongly suggesting adrenal hypofunction. Patients such as the one described here represent borderline cases probably more numerous and more responsive to therapeutic efforts than those with more conclusive clinical pictures.

T. C., a man of fifty-six, had suffered from dizzy spells, weakness, constant fatigue, and a gradual increase in skin pigmentation for six months. There was marked pigmentation of the forearms, neck, shoulders and legs. His blood pressure was 120 systolic, 80 diastolic, fasting blood sugar 75 mg. per cent, basal metabolism minus 21 per cent, red blood count 3,900,000 and hemoglobin 80 per cent. The sugar tolerance was as follows: fasting 81, one-half hour after the glucose 109, one hour 106, two hours 88 and four hours 93 mg. per cent. Plasma chlorides were 604 mg. per cent. No excess excretion of sodium could be demonstrated. The patient felt considerably better when given adrenal cortex substance by mouth or by injection. When sodium chloride was withdrawn his symptoms increased in severity. When given

large amounts of sodium chloride by mouth his strength improved and his blood pressure rose somewhat. He was able to walk to the clinic in forty minutes whereas formerly it had taken him one and one-half hours.

It would seem important in such patients at least to prescribe large amounts of salt in the hope of preventing progression of the disease. If further improvement can be obtained with the adrenal cortical hormone, its administration is indicated. Caution, however, must be maintained to avoid the tendency to see adrenal insufficiency in all patients with asthenia. The use of the hormone should be restricted to those cases in which there are definite indications.

BORDERLINE DIABETES

Not infrequently patients are seen with only slightly elevated blood sugar and minimal glycosuria. Glucose tolerance tests in such cases usually show mild or borderline types of diabetic curves. At this point we are confronted with a dilemma, emphasized by the recent trend toward higher carbohydrate diets in diabetes. Shall we restrict carbohydrate to spare a failing pancreas, or shall we force carbohydrate to stimulate the islets to increased production of insulin?

Formerly the discovery of a diabetic sugar-tolerance curve led promptly to strict curtailment of carbohydrate intake. We have recently reported observations indicating that some diabetics will gain tolerance on high carbohydrate, while others will lose tolerance.⁹ Studies upon the relative response to insulin offer hope that we may be able to distinguish diabetes which is primarily pancreatic from that which is largely extra-pancreatic. The relatively insulin-resistant diabetic who reacts as if his disease were at least partially extra-pancreatic in origin usually shows definite gains in tolerance with liberal carbohydrate. Those patients in the relatively insulin-sensitive group usually lose tolerance with excessive carbohydrate ingestion. An effort to determine the relative insulin sensitivity of the patient would therefore seem in-

licated before selecting the individual diet in borderline cases of diabetes.¹⁰

When a sugar-tolerance curve of the mild diabetic type is found it is well to take into consideration the possible effect of the patient's diet immediately preceding the test. It has been demonstrated that a starvation or high-fat diet decreases the glucose tolerance in normal subjects, while a high-carbohydrate diet raises the tolerance.¹¹ When careful study of tolerance curves is indicated we have found it useful to employ a preceding standard diet of 27 calories per kilogram body weight, containing 2 Gm. of carbohydrate per kilogram.

SPONTANEOUS HYPOGLYCEMIA

Hypoglycemia severe enough and protracted enough may provoke a chain of symptoms characterized by tachycardia, hunger, weakness, sweating, tremor, diplopia, mental confusion, sometimes delirium or convulsions, and finally coma. Hypoglycemic symptoms may occur in many conditions:

1. Excess of insulin.
 - (a) Therapeutic injections.
 - (b) Pancreatic islet tumor or hyperplasia.
 - (c) Functional hyperinsulinism.
2. Diminution in insulin-resistant factors.
 - (a) Adrenal disease (Addison's disease).
 - (b) Pituitary disease (Simmond's disease, pituitary tumors).
 - (c) Thyroid disease (myxedema).
3. Diminution of glycogen reserves.
 - (a) Starvation.
 - (b) Liver disease.
 - (c) Renal diabetes.
 - (d) Lactation.
 - (e) Muscle wasting or excessive muscular exercise.
4. Disturbance in central nervous system control of blood sugar.

Differential Diagnosis.—Patients suffering from spontaneous hypoglycemic attacks have been suspected of drunk-

eness, of having brain tumors, epilepsy, hysteria and various psychoses. The association of hunger and of relief by food is suggestive of hypoglycemia. The onset of the attacks with exertion and with fasting is characteristic. Sugar-tolerance tests are not reliable diagnostic aids since even diabetic type curves may be obtained as well as the more characteristic flat or depressed curve. Detection of a blood sugar below 40 mg. per cent during an attack and quick relief by intravenous glucose are conclusive evidence of hypoglycemia as the cause of the symptoms.

Following the establishment of the diagnosis of spontaneous hypoglycemia the determination of possible causes must be undertaken. There is at present a tendency to use too loosely the term "hyperinsulinism." It should be employed only in those cases in which no other cause can be demonstrated for the low blood sugar. Even after a probable diagnosis of hyperinsulinism is made an important decision remains. Is it functional or may an islet adenoma be present? Operative removal of such adenomata has resulted in cures in several cases.

Acute fulminating cases, in which loss of consciousness is frequent and intravenous dextrose is required, and in which there is no favorable response to diet should have exploratory operations. Certain puzzling borderline cases present real problems, as illustrated in this report:

W. B., a girl of twenty, had suffered from spells of extreme nervousness, and occasional attacks of loss of consciousness for four years. A typical attack began with nervousness, tremor, hunger, weakness and faintness. She would then burst into a profuse perspiration and slip into unconsciousness without preceding convulsions. Awakening after an hour or two she would be very weak, hungry and thirsty and would revive rapidly after taking food. She was slightly obese and had been gaining weight. Basal metabolism was minus 2 per cent. A glucose tolerance test showed practically no rise in the blood sugar: fasting, 66 mg. per cent; one-half hour, 69; one hour, 63; two hours, 67; three hours, 62. A fasting sugar of 55

mg. per cent was obtained at another time. During an attack the blood sugar was 72 mg. per cent but intravenous glucose promptly terminated a typical seizure usually lasting over an hour. A high-fat, low-carbohydrate diet was given with frequent feedings and no further attacks have occurred.

A diagnosis of functional hyperinsulinism was made in this case because of the prompt response to a diet designed to decrease the amount of insulin secreted.

ADRENAL CORTICAL TUMORS AND PITUITARY BASOPHILISM

Obesity, hypertension and decreased sugar tolerance are among the most common conditions encountered in medical practice. Frequently they occur in the same patient. The occurrence of various grades of hirsutism in women is not uncommon. Menstrual disturbances, especially amenorrhea, occur often in obese women. If the more common triad of obesity, hypertension and diabetes occurs in association with the rarer conditions of hirsutism and amenorrhea we have the symptom complex occurring in the adrenocortical syndrome and the indistinguishable "pituitary basophilism." Since in certain cases removal of adrenal tumors¹² or roentgen therapy to the pituitary¹³ has resulted in relief, every effort should be made to diagnose these more serious conditions from the more frequent borderline cases which resemble them. The problem is further complicated by the possibility of another uncommon tumor which may cause amenorrhea and hirsutism, the ovarian arrhenoblastoma.¹⁴

Our differential diagnostic methods are at best gross and inadequate in these conditions. In all such cases both positive and negative evidence should be considered.

The ovary is the most accessible to examination. Gynecologic examination may reveal a tumor of the ovary which can be removed. Complete amenorrhea with deep male voice, assumption of male contours, enlarged clitoris, and atrophy of the breasts are much more suggestive of arrhenoblastoma than of pituitary or adrenal disease.

The pituitary and adrenal are more difficult to examine.

Local pressure changes in the presence of a pituitary neoplasm may cause headaches, visual failure, constriction of the visual fields, or roentgenographic alterations in the sella turcica. However, most of the basophilic adenomata described have been very small and such neighborhood signs have not occurred. Frank diabetes or a prediabetic state may occur either with adrenal cortical tumors or pituitary disease. The basal metabolic rate may be at any level, from that of myxedema to that of hyperthyroidism, but is usually normal. A palpable mass may be present in the loin in the larger adrenal neoplasms, but only a small adenoma or simple hyperplasia may be present. Obesity of the "buffalo" or "Humpty-Dumpty" type, confined to face, neck, and trunk, purplish abdominal striae, osteoporosis, polycythemia, exophthalmos, and purpura have been described as particularly suggestive of pituitary basophilism.

It is questionable whether symptomatically the pituitary can be distinguished from the adrenal syndrome. Whenever definite signs point to one or the other organ, therapy may be correspondingly directed. From the present evidence it seems that either gland may initiate the changes described.

SUMMARY

The chief value of the rapidly accumulating knowledge of the endocrine glands should be in the better understanding of minor or moderate functional deviations from the normal. The good response to therapy and the frequency of the less severe glandular disturbances makes it important to keep them in mind.

That endocrine disorders may not present classical syndromes deserves emphasis. A few cases are presented illustrating signs and symptoms probably occurring frequently but usually neglected in endocrine diagnosis.

CLINIC OF DR. MAX DEUTCH

WASHINGTON UNIVERSITY SCHOOL OF MEDICINE

THE DIAGNOSIS AND TREATMENT OF ENDOCRINE INFANTILISM

DWARFISM is the normal occurrence in the various tribes of pygmies that are scattered through Africa and various Asiatic islands. Pygmies usually attain a height of 4 to 4½ feet in adult life, mature sexually at the age of ten or eleven years, are short-lived, dying as a rule at the age of about forty, and retain throughout their lives the infantile proportions of short limbs and relatively long torso. Their features in the face, hands, and feet are distinctly simian in type and they are considered by anthropologists as of very remote origin.¹

A normal type of dwarfism is seen occasionally as a familial feature, possibly as an atavistic phenomenon. We have had the opportunity of observing some of the members of such a family in which the somatic hypoplasia is seen to be transmitted through normal as well as dwarfed members of the family, as seen in the accompanying genealogic tree (Fig. 15). The dwarfed members of this family were very small at birth, as far as could be determined, weighing only 4½ to 5½ pounds, although full term. None of them show any evidence of glandular disease. As regards function and span of life they lead normal lives. The adult members have extremities somewhat short relative to the length of the trunk. In the one adult who has been studied roentgenologically, the bone development is normal. In all four of the children who have been x-rayed, there is distinct evidence of delay in the

appearance of the centers of ossification as compared with children of average normal size.

Very striking instances of sporadic dwarfism occurring in families of average stature have been reported. One of the first records was by von Hanseemann² in 1902, who studied a professional midget. This man, at twenty-two years, was 3 feet 10 inches in height, had normal adult proportions, normal bone development, normal hair growth on face and pubes; and although the testes were not palpable, he gave a history of nocturnal emissions, suggesting at least normal interstitial

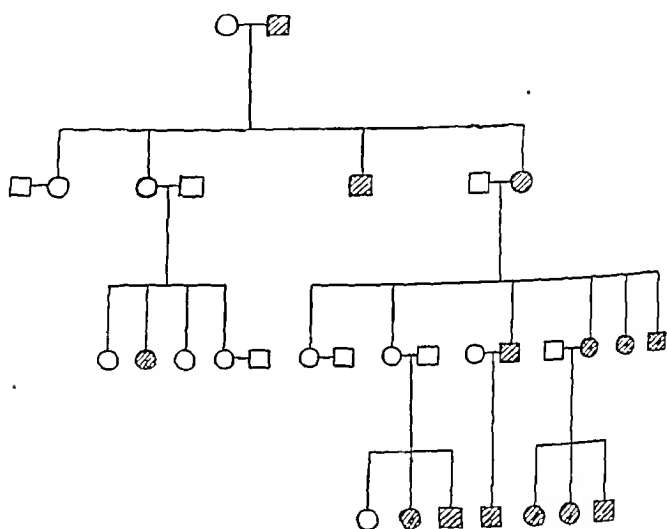

Fig. 15.—Familial somatic hypoplasia. The shaded symbols indicate subnormal size, the adult members being 5 feet or less.

cell function. Von Hanseemann called this type "Primordial Dwarfism," and thought it was probably due to an ovum defect.

Dwarfism is also associated with congenital bony or cartilaginous anomalies. Of these the most common is chondrodystrophia fetalis, in which the shortness in stature is considered due primarily to defective cartilage formation, particularly at the ends of the long bones. The bones themselves are widened and deficient in calcium. Other congenital bone defects, such as cleidocranial dysostosis and osteogenesis im-

perfecta, may be accompanied by dwarfing. Of the acquired bone diseases, rickets, whether due to vitamin D deficiency, renal disease, or celiac disease, may be responsible for marked stunting of growth. Dwarfing also may occur in diabetes, congenital syphilis, and congenital heart disease; in fact, as a result of any severe chronic or recurrent disease in childhood.

To be distinguished from mere dwarfing in stature is the condition of infantilism. This term should be restricted to those who are not only considerably below standard size but who also exhibit retarded sexual development. Often such individuals also retain the infantile body proportions with relatively short extremities as compared to the trunk. (Normally the pubic height becomes equal to the upper measurement, from vertex to pubis, at twelve to fourteen years.)

True infantilism has been reported to accompany hemolytic icterus at times. Langston³ recently reported a boy, whose growth became retarded at the age of seven years, and whose development ceased entirely at the age of eleven. At the age of eighteen years, he was not quite 5 feet in height. In addition to anemia, icterus, splenomegaly, and increased red cell fragility, he had marked sexual underdevelopment as regards genitalia and hair growth. His bony development was markedly retarded. Following splenectomy he was given antuitrin G and the pregnancy urine extract, but in amounts hardly sufficient to account for a growth of 6½ inches in height and the occurrence of sexual maturity in the two years following the splenectomy.

In the presence of von Gierke's disease, which is a syndrome of hepatomegaly and deficient glycogenolysis, infantilism in 3 siblings was recently reported,⁴ the most marked case being in the oldest, a boy of eighteen years who, although normal at birth, began to slow up in his growth at the age of three and one-half years, at which time a large liver was first noted. At the age of eighteen he had the appearance, size, proportions, and sexual development of an eight-year-old.

Cretinism has long been recognized as a type of infantilism

of endocrine origin. The striking efficacy of thyroid extract in most cases is well known. The accompanying chart (Fig. 16) illustrates this remarkable effect on growth in a typical cretin who was first seen in the pediatric clinic at the age of five and one-half years, but whose mother did not carry out the directed treatment until the child's return to the clinic five years later.

Fig. 16.—Effect of thyroid therapy on growth rate of a cretin. Shaded strips indicate periods of thyroid administration.

The occurrence of stunted growth in a child with hypothyroidism even in the absence of cretinism is illustrated by the following case.

This child (Fig. 17), Marilyn P., was first seen in the pediatric clinic October 18, 1932, at the age of eleven and one-half months, because of anorexia and short stature. The mother, twenty-two years, is of average stature; the father, a man of twenty-four, is somewhat below average size. A paternal aunt has a colloid goiter and is overweight. A maternal second cousin has hyperthyroidism. The child was

born about one week beyond the calculated term after a normal pregnancy, weighing $5\frac{1}{4}$ pounds at birth. She was a normal baby except for the small size, and did well on breast feedings until the age of five weeks, when she began to vomit projectily. The vomiting ceased shortly after a pyloroplasty at the age of six weeks, but she has remained a feeding prob-

Fig. 17.—Marilyn P. Hypothyroid dwarfism without cretinism.

lem ever since. She has been markedly constipated, the bowels moving as a rule only once in three days. Her skin has always been dry. Her development is retarded. She cut a tooth at ten and one-half months, and at the age of eleven and one-half months did not sit up alone. Because of the dry skin and constipation she had been given thyroid ex-

tract in doses of $\frac{1}{4}$ to 1 grain three times a day for irregular periods totalling about three months. Thyroid had been administered for only short periods at a time because it resulted regularly in excessive sweating, restlessness and sleeplessness.

Between October, 1932, and January, 1935, she was seen at irregular intervals in the pediatric clinic and in Children's Hospital. During this time she was given thyroid extract (Armour) in doses of from 1 to 3 grains daily at various times for a total of seven months. Rather quickly, however, she developed signs of nervousness, sweating, sleeplessness, and hair loss, with little or no improvement in appetite; and although growth improved, there was very little gain in weight.

Since January 15, 1935, the child has been under close observation in the endocrine clinic, and the mother has been very cooperative so that careful observation for over a year has been possible. At the start of this period, the patient, aged three years two and one-half months, weighed 22 pounds 7 ounces and measured 32 inches (average height for eighteen months). Her nutrition was fair, the weight being only $1\frac{1}{2}$ pounds below the average for her height. The facial expression was dull, the features full, but without the retrousse nose or large tongue characteristic of cretins. Epicanthic folds and a slight incurvation of the little finger were present, but other signs of mongoloidism were absent. The skin of the face, neck, back, and especially the hands was dry. The hair also was somewhat dry, especially over the occiput. The fingers were not the stubby digits of cretinism. All the deciduous teeth were present. The heart and lungs were normal. The abdomen exhibited a right rectus scar at the site of the pyloroplasty; abdominal prominence was not excessive. No organs or masses were palpable in the abdomen. The external genitalia were normal. Mentally she was obviously retarded.

Hemoglobin, 65 per cent; red blood corpuscles, 3,450,000. Serum cholesterol, 572 mg. per 100 cc. x-Rays of the wrists taken on August 29, 1934, at the age of two and $10/12$ years showed only 1 carpal center, no centers for the heads of phalanges, metacarpals, or lower end of radius, although on

February 14, 1935 (aged three years three and one-half months) most of the latter centers, as well as a rudimentary second carpal center, had appeared (Fig. 18).

February 5, 1935, after she had been without thyroid for four months, the administration of $\frac{1}{8}$ grain daily of thyroid extract (Armour) was begun. She was kept on this for one

Fig. 18.—Marilyn P. x-Rays of hand and wrist at two and ten-twelfths years (a) and three and three-twelfths years (b), showing delay in bone development. At three years there normally are present three well-developed centers in the carpus and all the centers at the ends of the phalanges and metacarpals.

month and then reduced to $\frac{1}{10}$ grain daily because of restlessness and excessive perspiration. Her appetite improved, her bowels were less constipated, the cholesterol dropped to 202 mg. on March 4, 1935. Her height in the course of three months increased $\frac{1}{4}$ inch. The skin and hair became distinctly less dry.

After two weeks without specific medication, the administration of the thyrotropic growth factor of the anterior pituitary (Phyone)* was begun, starting with 0.25 cc. subcutaneously, and increasing to 1.5 cc. In the course of five weeks she was given 26 injections totalling 26.5 cc. During this period improvement continued as regards skin and hair texture and bowel regularity. There was also about $\frac{1}{2}$ pound gain in weight. The cholesterol rose, however, to 400 mg. and

Fig. 19.—Marilyn P. Effect of thyroid therapy on growth rate. Shaded strips indicate periods of thyroid administration.

there was no increase in height. The child then remained away from the clinic for four and one-half months, getting no specific treatment during this period. She gained 12 ounces during this time, but did not grow taller. She was having a normal bowel movement every two days. The hair over the occiput was rather dry, the skin of the upper extremities was fairly dry and of the back very dry. During the next six

* Supplied to us by Wilson and Co.

months she was constantly on thyroid. This was started as $\frac{1}{8}$ grain daily (Armour) and slowly increased to $\frac{3}{8}$ grain daily. Since the latter dosage was accompanied by symptoms of sweating, irritability, and sleeplessness, the amount was reduced to $\frac{1}{4}$ grain daily. During this six months' period the patient has shown very considerable improvement. She has grown $1\frac{1}{2}$ inches, which is slightly above the normal rate of growth for this age (four years) (Fig. 19). She has gained almost 2 pounds and has begun to walk and talk. Her bowel movements occur every one or two days. There is still slight dryness of the hair over the occiput and the skin of the back. x-Ray of the wrists still shows considerable retardation; and the child's height at the age of four years five months is the average for a two-year-old. She has been walking since the age of four.

Briefly, then, this child, who was rather small at birth, has remained considerably undersized, and although not presenting the appearance of cretinism has many other typical signs of hypothyroidism: mental deficiency, dry hair and skin, constipation, anemia, delayed bone development, and high cholesterol. She has shown her greatest period of improvement during a six months' period on very small doses of thyroid, carefully regulated so as to minimize overdosage effects. Extreme sensitivity to overdosage of thyroid in cretins⁵ as opposed to the high tolerance of normal children⁶ is well known.

It is my feeling that this patient can be considered as an instance of hypothyroid dwarfism despite the absence of cretinism. Other cases of this type of "nanosomia hypothyrotica" in later life have been described by Sternberg.⁷ Wells⁸ described the postmortem examination of a seventy-two-year-old, mentally retarded dwarf, who showed none of the features of cretinism although the only thyroid tissue found postmortem was an atrophic cystic lingual goiter. Hypothyroid infantilism without cretinism appears to be rare.

Of greater interest is infantilism of hypophyseal origin, reports of which have become increasingly frequent in the

literature since the isolation of growth factors from the anterior lobe of the hypophysis.^{9, 10} This type of infantilism is known variously as Paltauf dwarfism¹¹ or the Lorain-Levi type of infantilism,¹² although it was really Gilford¹³ who, in introducing the term "ateleiosis," first suggested that the condition was probably of pituitary origin.

Patients with pituitary infantilism may be normal at birth. They develop and grow normally until sometime in childhood, when growth and sex development cease or become greatly retarded. The age of onset is usually between eight and twelve years, but sometimes as early as one year, sometimes as late as fifteen years. Some cases may resume their growth after a period of years, in what would ordinarily be considered adult age. As part of the sexual underdevelopment, there is characteristically a marked delay in epiphyseal closure, although the time of appearance of the centers of ossification is normal. There have been few cases of this condition which have been studied postmortem, the majority revealing tumor destruction or compression of the pituitary, others with Rathke's pouch or craniopharyngeal duct tumors in which the pituitary has shown little or no histological change.¹⁴ Three somewhat atypical cases have been reported in which there were midbrain tumors with no histological change in the pituitary.¹⁵ The cases reported clinically are greater in number than the pathologically studied cases, and of these very few have shown evidence of tumor or other destructive intracranial lesions. The following case is clinically typical of hypophyseal infantilism.

This girl, Lillian S. (Fig. 20), was referred to the endocrine clinic December 6, 1934, at the age of sixteen years because of failure to grow. Her mother and father were both of average size. The patient was born at full term and was apparently normal. Her development and growth in infancy were normal. When she was seen in the pediatric clinic at the age of eight years because of chronic otitis media, no deficiency in stature was noted. At the age of twelve years, the child's growth almost ceased, although there apparently had

been a growth of 1 inch in the nine months preceding her entrance into the endocrine clinic. She had never menstruated. Frontal headaches, usually in the evening, had been

Fig. 20 —Lillian S., aged sixteen years. Hypophyseal infantilism with dwarfism and sexual underdevelopment.

present for about two years. Examination: height, 52 inches; pubic height, $26\frac{1}{2}$ inches; weight, 73 pounds. She was well nourished and presented the appearance and approximate body proportions of a ten-year-old. There was slight fatty fullness

over the breasts, abdomen, and buttocks. The external genitalia appeared normal for a girl of nine or ten years. There were a few sparse hairs over the labia majora. The uterus (rectal examination) was infantile. The skin was warm, moist, smooth. The hair of the head was normal. A few sparse axillary hairs were present. The facial expression was rather mature, the features small, with pointed nose and chin, high narrow palatine arch, and crowded teeth. There was a chronic otitis media and chronic tonsillitis. Heart and lungs were normal. The blood pressure was 110/80. The eyes and eyegrounds were normal except for hyperopia, with vision of 6/60 in each eye. The visual fields have not as yet been determined. The I. Q. was 84.

Basal metabolism, + 17. Wassermann and Kahn, negative. Urine contained sugar on one occasion. Stereogram of skull showed a small, bridged sella turcica. The bones of the skull, face, and cervical spine were of delicate structure. A lateral view of the elbow revealed partial union of the head of the radius, nonunion of the olecranon. The hand and wrist showed normal bone development. However, there was no union of any of the centers at the ends of the phalanges and metacarpals or lower ends of radius and ulna.

During a period of six months' observation without specific medication, the patient grew only 1 cm. (0.4 inch). The subcutaneous administration of anterior pituitary hormone (Phyone) was then begun.* She was given 1 to 2 cc. two to three times weekly for a period of three months, a total of 48 cc. being administered. About this time the patient developed a pathological depression because of home factors and treatment could not be continued. A check of her measurements on April 7, 1935, ten months after the start of endocrine therapy, revealed a growth of only 1 cm. (0.4 inch) in this period.† x-Ray of the hand and wrist at this time (age seventeen and one-half years) showed no change from the ap-

* Under the supervision of Dr. Cyril M. MacBryde.

† The measurements of both patients were made by Dr. Cecil M. Charles of the Department of Anatomy.

pearance one and one-half years before (Fig. 21). Her general appearance was unaffected except for a slight increase in the amount of pubic hair.

This patient, it is seen, showed no beneficial effect of the pituitary therapy, which was probably grossly insufficient. Since many of the injections were accompanied by moderately

Fig. 21.—Lillian S., aged sixteen years. x-Ray of hand and wrist, showing nonunion of epiphyses. The same appearance is found in a film taken one and one-half years later. Union of all the centers at the ends of phalanges and metacarpals is normally complete at fifteen to sixteen years.

severe local reactions, administration of larger amounts than 2 cc. was not attempted.

Reports on the effectiveness of growth hormone have shown a great variation in individual cases. Using pituitary extracts relatively high in growth-promoting principle, Shelton and his coworkers have noted varying degrees of refractoriness in their patients. As a rule, the older the patient the more

refractory he was, irrespective of the status of his epiphyses.¹⁶ Furthermore, all children show variations in the growth curve from year to year, and particularly from month to month, the growth increment being greater in the semester of April to September. In considering the effectiveness of any therapy in stimulating growth, not only must this be borne in mind, but also at least six months' control period before and after therapeutic courses should be carried out in order to judge the effectiveness of the therapy. The best results in stimulating growth have been reported in individuals who received thyroid as well as growth hormone.¹⁷

In the administration of thyroid gland, particularly to children, two principles must be borne in mind. (1) Children with hypothyroidism are sensitive to overdosage effects. The initial dose should therefore be low, preferably not more than $\frac{1}{4}$ grain daily of the desiccated gland. (2) There is no satisfactory criterion for the amount of thyroid that should be given except the clinical reaction of the patient. Since the overdosage effects that may result are temporary and subside within a few days after discontinuing treatment, it seems reasonable to increase the daily dosage of thyroid at intervals of two to four weeks until manifestations of overdosage do appear.

Therapy with the growth factor is still in an unsatisfactory state. On the basis of body weight, results in human beings to be comparable with those in experimental animals would require the administration of enormous amounts of the extract. If possible, injections of 2 cc. daily or every other day should be given deep subcutaneously, although smaller doses ($\frac{1}{4}$ to $\frac{1}{2}$ cc.) should be used at the start because of the local reactions in some individuals. Hartmann¹⁸ has suggested that the growth hormone be given on alternate months so as to minimize the formation, if such does occur, of "anti-hormone." As a matter of fact, of several undersized diabetic children whom he has treated, the only one in whom a possible growth stimulation occurred was a boy that was treated in this fashion.

CLINIC OF DR. HAROLD A. BULGER

FROM THE DEPARTMENT OF MEDICINE, WASHINGTON UNIVERSITY SCHOOL OF MEDICINE AND THE BARNES HOSPITAL

ENDOCRINE OBESITY

CLINICAL experiences repeatedly suggest a relationship of obesity to the endocrine glands. To postulate such a relationship seems rational. It is clear that various endocrine organs may have a more or less striking influence on metabolic processes. They may cause variations in the total energy expenditure or defects in intermediary metabolism. Certain hormones have characteristic effects on specific cells and therefore might be expected to act locally on adipose tissue.

Early expectations that diminished combustion from thyroid insufficiency would explain all obesity have proved a delusion. Hypothyroidism is rarely, if ever, a primary cause of marked obesity. A lowered specific dynamic action of foods had been postulated as an explanation for a conservation of calories. Certain of the endocrine glands have been thought to exert such an influence. The most careful investigations, however, have not presented evidence that this in itself was an adequate explanation. An exaggerated drop in metabolic rate after exercise or food to below figures considered the basal rate has been noted in obesity, and purported to be significant. However, such "negative phases" are elusive in obesity and striking examples may be found in undernutrition.

Body weight is maintained at a remarkably constant level in the great majority of normal individuals. This significant fact tends to be true even with markedly different habits of

activity and food consumption. It seems obvious that food intake cannot be so delicately regulated that day by day it would just balance the actual requirements for activity. Appetite could not possibly discern the slight variations in caloric intake which would be necessary. The "factor of safety" possessed by various structures and functions of the body is well known. One might suggest that a "factor of safety" is operative in regard to the food intake. Food intake may always tend to be greater than is actually necessary for activity, and other metabolic needs. One might postulate that, normally, there are mechanisms which may limit the storage of food and dissipate excess calories. Abnormalities of these mechanisms would result in states of undernutrition or obesity. It is conceivable that the abnormality may be located in the stores, in the adipose tissue itself.

The usual response of starvation or inadequate food intake is a lowering of the basal metabolic rate. This at once suggests a means by which body weight may be automatically regulated. An increase in metabolic rate with excessive food intake had been noted in animals. This has been discussed at great length and is usually referred to as "luxus consumption." It has been inferred that this effect may be influenced by the endocrine glands. The subject has received little attention from this point of view. Studies have suggested that "luxus consumption" no longer occurs after thyroidectomy. The effect is said to be normal after removing the gonads. It seems, however, that a phenomenon as simple as "luxus consumption" is not prominent in the human body. While undernutrition decisively lowers the basal metabolic rate, an excessive food intake, in experimental studies, has not produced a significant rise.

Two cases are presented, chiefly to illustrate the difficulty of detecting a metabolic explanation of obesity. The two girls are of comparable ages. Their histories are similar except that one developed marked obesity, the other emaciation. They were both referred to the endocrine clinic, as they were thought to have endocrine abnormalities.

Case I was a sixteen-year-old girl. At thirteen years, menstruations started. They were regular and normal. Then, after about a year, they became scanty and finally amenorrhea developed. Her weight had always seemed normal. At thirteen she weighed 120 pounds. Some time after that she began to gain weight rapidly. When first seen she weighed 204 pounds. She had obscure painful areas over various parts of the body. All evidence indicated that she was not a big eater; appetite was considered to be rather poor. Her school history indicated definite personality changes during this time. The school nurse found her temperature slightly elevated over long periods. Before the onset of these disturbances, she had had an illness lasting several months which may have been encephalitis. A sister had had a "nervous breakdown."

Although she appeared sturdy and strong, there was actually considerable asthenia. There was nothing notable about the distribution of the adipose tissue. The development of the secondary sex characteristics seemed normal. Pubic hair extended up over the lower abdomen. There were rose-colored striae over the abdomen and upper arms. Blood pressure was usually a little elevated; average about 136/90. There were changes in skin circulation, varying from a definite diffuse pink flush to mottled areas of cyanosis. There was no tendency to ecchymosis. The sugar tolerance curve was as follows: fasting, 82 mg. per cent; one-half hour, 261; one hour, 192; two hours, 73, and three hours, 82. The basal metabolic rate was moderately elevated (+17 to +25 per cent).

Case II was a girl sixteen years old. At fourteen years, menstruations started. After a little more than a year amenorrhea developed. She had been a rather small girl, at eleven years weighing only 87 pounds. With the onset of menstruations she started to gain weight rapidly until she reached 129 pounds. Then, before the amenorrhea started, she began to lose weight; weight fell to 89 pounds. There had been no striking change in food intake; appetite was good. Her

activity and food consumption. It seems obvious that food intake cannot be so delicately regulated that day by day it would just balance the actual requirements for activity. Appetite could not possibly discern the slight variations in caloric intake which would be necessary. The "factor of safety" possessed by various structures and functions of the body is well known. Their histories are similar except that one developed marked obesity, the other emaciation. They were both referred to the endocrine clinic, as they were thought to have endocrine abnormalities.

hips, buttocks and upper thighs. Overdevelopment in these locations, when the obesity is not marked, may occasionally appear significant. Usually, however, they are obscured by the more general fat accumulation.

More difficult to discuss are the variations in firmness and resilience of adipose tissue. These, combined with differences in strength and tension of the supporting tissues, may result

Fig. 22.—Comparing metabolic studies on Cases I and II. They show the respiratory quotients and the percentage change in calories per hour after glucose.

in apparent changes in distribution. One frequently sees diagnostic significance attached to these aspects, but in reality they seem to be related more to age, general physical condition, or duration of obesity. There is another obscure effect in which gravity appears to play a part. We refer to the increase in adipose tissue in dependent parts. This seems to occur at times even when the upper parts of the body are

family insisted there had been a noticeable gain in height between the ages of fourteen and sixteen years.

There was nothing of note in her early history except a tendency to constipation. One sister had been operated on for a goiter. Another sister had developed amenorrhea at about the same age as the patient and had become moderately obese at the time. Later she reverted back to normal health.

This patient presented nothing of special note on examination except the obvious thinness. Blood pressure tended to be low, average about 98/54. The sugar tolerance curve was low: fasting, 76 mg. per cent; one hour, 90; two hours, 105; three hours, 87. The basal metabolic rate was moderately low (-17 to -22 per cent).

Some metabolic studies on these two patients are shown in Fig. 22. The basal metabolic rate of the patient with obesity was elevated; that of the patient who had been losing weight was low. The fasting respiratory quotients and the respiratory quotients after glucose were about the same in the two patients. The undernourished patient rather than the obese patient presented a good illustration of a "negative phase" of the metabolic rate following the specific dynamic action of glucose.

Many writers, seemingly with the greatest confidence, attach vast significance to variations in the distribution of fat. One pleads for a more critical attitude. Constitutional make-up is probably the greatest of the factors influencing the pattern of fat distribution. As inheritance determines such features as stature and character of the hair, it must determine the form of the deposits of adipose tissue. About two thirds of the individuals with obesity have a family history of corpulence. Local fat accumulation seems related to the activity of the gonads. One notes the development of adipose tissue in certain areas giving the body the contours which are such important features of the secondary sex characteristics. This development is more striking and typical in the female. The particular areas responding to this influence are the regions of the breasts, shoulder girdles, umbilicus, mons veneris.

The symptomatology, in addition to the obesity, presents a tendency toward genital dystrophy, and in children abnormalities in growth. There are often variations in carbohydrate metabolism. Features vary according to the age of onset. In infancy and childhood before puberty, it is characterized chiefly by the obesity. Any evidence of genital dystrophy, of course, would hardly be expected. In this period we find the tendencies toward abnormal growth. Rarely is the stature less than normal. Frequently there is a period of increased rate of growth. Sometimes this may be quite striking. When fully developed, however, these patients are seldom abnormally tall and are often below the average height because epiphyseal closure occurs prematurely and results in an early cessation of growth. Sluggishness and somnolence are common. In the early stages, the sugar tolerance curve may be higher than normal.

Later on, around the age of puberty, changes relative to the secondary sex characteristics become evident. There is a more or less marked tendency for the sex organs to be underdeveloped, although it is not unusual for the development to occur several years earlier than normal. In males the axillary and pubic hair is scant or absent. Adipose tissue at first may increase in the regions of the breasts, mons veneris and hips, giving to the male the configurations of a female. As the obesity becomes more marked, however, these contours may become obscured. In the female there is a tendency toward amenorrhea. One often obtains a history of normal or excessive menstruation and periods of amenorrhea. Related, perhaps, to the transient periods of increased stimulation of development, one may find great variation in the size of the breasts. In some female cases there is little or no enlargement, while in others there is excessive development along with an exaggeration of other female contours by hypertrophied adipose tissue. Whereas, as noted above, there may be, early in the course, an elevated sugar tolerance curve, a flat curve is characteristic of this period. Here again there seems to be a suggestion of deviation from normal in both

becoming thinner. This tendency was recognized by Benjamin Franklin when he wrote in his famed letter to a young man, "The face first grows lank and wrinkled—then the neck, then the breasts and arms—the lower parts continuing to the last as plump as ever: so that covering all above with a basket and regarding only what is below the girdle, it is impossible of two women to know an old from a young one." The condition known as lipodystrophy may be an exaggeration of this phenomenon. Such transitions in obesity are probably not uncommon. Should we not, therefore, be more critical regarding the diagnostic significance of adiposity of the extremities? One should also keep in mind the fact that edema, myxedema tissue, atrophy of the muscles, etc., may modify the form of the obese individual.

One large group of adiposities may be considered as a whole. They seem, possibly, related directly or indirectly to the endocrine system. The clinical pictures suggest that they may be variants of the same fundamental disorder. Various designations have been applied to members of this group: cerebral adiposity, adiposogenital, dystrophia adiposogenitalis, syndrome hypophysaire adiposogenital, Fröhlich's syndrome, adiposis dolorosa, Dercum's syndrome, etc. Etiologically, there is evidence for the involvement of related mechanisms. Hypophyseal tumors are found in this group. There are other types of intracranial tumors. The most common are craniopharyngiomas, congenital tumors of Rathke's pouch, exerting pressure on the pituitary and the hypothalamus. There are rare cases with pineal tumors. Cases have clearly followed encephalitis where the centers in the base of the brain are characteristically involved. They have followed chorea. Many cases occur during growth. It is not entirely irrational to postulate instability of the hypothalamus mechanisms during this period. One can also postulate effects on an hypothalamohypophyseal mechanism secondary to other marked endocrine disturbances; for example, in the extreme adiposities which have rarely followed complete oophorectomy in women.

obesity. Slight to moderate obesity is a characteristic part of the picture associated with increased cortico-adrenal activity, while undernutrition is the tendency in adrenal insufficiency. The rare association of obesity and pineal tumors has been noted above. Animal experiments have indicated that removing the gonads will not cause obesity. However, the changes in adipose tissue at puberty, the tendency toward obesity at the menopause, and the occasional marked obesity of castrates suggest some relation to the sex glands. This relation is possibly due to secondary changes initiated in other endocrine glands or the nervous system. It is conceivable that all marked adiposities are intimately related to abnormalities of the neurohypophyseal mechanisms.

Concerning treatment, the chief point to emphasize, at the present time, is that there should be a more conservative use of drugs and more radical use of diets. It would seem that thyroid should not be used except when there is sluggish mental activity and a distinctly low basal metabolic rate. One notes that it is a common practice to give thyroid to a rapidly growing, slightly obese adolescent, with a moderately lowered metabolic rate, although appearing healthy, active and alert mentally. One doubts that this is advisable. There is no knowledge as to what extent such tinkering may upset neuro-endocrine equilibria. There is nothing to note regarding any efficacy of other endocrine preparations. It seems obvious that dinitrophenol should not be used in the treatment of obesity.

The most important consideration in the treatment of obesity is dietotherapy. Patients must be made to utilize their stores of fat. With marked obesity this will mean a most radical dietary regimen. One should aim to give adequate protein, vitamins and salts with almost no fat and minimal amounts of carbohydrate. One Gm. of protein per kilogram of estimated normal weight will be adequate. The diet should include a pint of skimmed milk daily and citrus fruits. It may be advisable to include haliver oil and yeast. Low carbohydrate vegetables, of course, are given. In the extreme

directions. We have been impressed by the number of cases of severe diabetes in girls with overdevelopment of the female characteristics, moderate obesity, and amenorrhea. They probably belong to this group. One should note the tendency toward abnormal levels of body temperature, delicate skin, small terminal phalanges, small thin fingernails, and genu valgum.

In adults the features other than marked obesity are less striking. Female sexual changes are indicated by the tendency toward amenorrhea. In males the fat deposits may have the same feminine distribution and the sex organs may suggest some reversion toward the infantile type. In this group, and less frequently in the younger groups, pain, both spontaneous and induced by pressure, may occur in the adipose tissue. It seems that tender areas may precede the development of lipoma-like deposits. Case I, described above, had painful adiposity and frequent mysterious attacks of pain in various locations. In one of these attacks her appendix was removed at another hospital. In the skin we have noted flushing, at other times mottled areas of cyanosis. Sometimes there may be purpura. Disturbances of the nervous system are not uncommon. Insanity occasionally occurs.

As to the course pursued by this group of marked adiposities, there seems to be, at least occasionally, a tendency to revert back to normal. Children with marked obesity, presumably of this type, have later seemed normal. What may be mild degrees of neurohypophyseal obesity in early adolescence is followed by normal adulthood. We have noted histories of adiposity and amenorrhea during adolescence in patients who later seemed normal and bore children. Adults with marked obesity sometimes revert toward more normal states of nutrition. We suspect that improvement attributed to endocrine therapy may often have been an illustration of the natural course of neurohypophyseal obesity.

More or less striking obesity may at times appear to be related to some specific endocrine gland. Hyperinsulinism probably gives us the best examples of so-called "exogenous"

obesity. Slight to moderate obesity is a characteristic part of the picture associated with increased cortico-adrenal activity, while undernutrition is the tendency in adrenal insufficiency. The rare association of obesity and pineal tumors has been noted above. Animal experiments have indicated that removing the gonads will not cause obesity. CLINIC OF DRS. DAVID P. BARR AND KURT
MANSBACHER

FROM THE DEPARTMENT OF MEDICINE, WASHINGTON UNI-
VERSITY SCHOOL OF MEDICINE AND THE BARNES HOSPITAL

THE TREATMENT OF PITUITARY INSUFFICIENCY
AND PITUITARY HYPERFUNCTION

HYPOPITUITARISM

IN spite of the great advance in our knowledge of pituitary anatomy and physiology the treatment of clinical disorders of the gland is far from satisfactory. The reasons are numerous.

Recent studies of the pituitary have demonstrated the complexity of its action. The number of separate effects suggested by physiologists is so great as to lead to actual confusion. In one or other of the many laboratories in which investigations are now being made, growth, thyrotropic, adrenotropic, galactagogue, ketogenic and diabetogenic fractions have been prepared. This list does not include the gonadotropic or sex-stimulating hormones of which three with definite and distinct actions have been suggested nor does it take account of the substance obtained from pregnancy urine which has been variously named prolan, antuitrin S and follutein and which has an action quite similar to one of the gonadotropic hormones of the pituitary.

None of these extracts is entirely protein free and each potent fraction exhibits to a greater or less extent more than one effect. For instance, most of the extracts thus far obtained, whether designed to exert growth, thyrotropic or galactagogue action, appear to have some diabetogenic activity.

cases sugar, bread and potatoes may be excluded. In other words, one is approaching caloric starvation without protein starvation. Patients may be taught to make a bread substitute, such as low-carbohydrate, fat-free bran muffins. Great pains are necessary in instructing the patient and in obtaining perfect cooperation. With less extreme types of obesity and as reasonable weight is approached, the diet may be more liberal.

In a discussion of endocrine obesity one should note that lipomatosis of varying degree may be observed in different types of endocrine disease. Lipomatosis may be accompanied by more or less marked constitutional symptoms. Nervous manifestations are sometimes prominent. Insanity may complicate the picture. Menstrual disturbances frequently occur. Sometimes the development of these fatty tumors seem related to the menopause. There are rare conditions of diffuse symmetrical lipomatosis. They are usually suspected of being "endocrine" in origin. The bizarre deposits usually occur above the level of the girdle. Sometimes they are confined to the cervical region. With these conditions, the remainder of the body may be surprisingly thin.

Concluding, let us suggest that the great majority of cases considered endocrine obesity do not fall into groups of distinct, clearly defined entities but are variants of a common morbid process. Differences in the age of onset, in inherited constitutional factors together with fluctuations of various neuro-endocrine influences result in extremely varied clinical pictures.

even among individuals of the same species. Thus the demonstration that a particular preparation will exert important physiological actions in a laboratory animal is not sufficient evidence to indicate that it will accomplish similar effects in man. Even when two species are similarly affected, the required dosage may vary widely. Relative weights offer no valid criterion for estimating the amount to give.

In all available animals the pituitary gland is so small and the yield of active material is so slight that commercial extracts have a prohibitive cost. Assuming equal sensitiveness of species, the relatively small amounts which may be physiologically effective in a rat must be multiplied several hundred times to accomplish the same action in man. It has been calculated with one of the best so-called "growth" extracts that it would be necessary to administer a daily dose of approximately 50 cc. in order to accomplish in a small man the effect which can be demonstrated so dramatically in laboratory animals.

Not the least of the factors which have delayed effective replacement therapy in man are the relative rarity of well-marked and accurately recognizable cases of pituitary insufficiency and the delay in establishing definite criteria by which to identify pituitary participation in borderline conditions. Even in the advanced cases, our methods for evaluating clinical action of extracts are crude and inexact and it is quite possible that in some instances beneficial effects of active hormones are entirely missed while in others favorable psychological response on the part of the patient may lead the physician to unjustified optimism.

At the present time the list of pituitary preparations commercially available is long, the nomenclature adopted by the various manufacturers is confusing and the claims are extraordinary and in many instances absurd. Some products are almost or entirely inactive: others have an activity sufficient to produce effects in small animals but are so weak as to exhibit no clinical benefit in the doses which are recommended and economically feasible. A few preparations pro-

The most carefully prepared galactagogue hormone may influence growth and may possess maximum adrenotropic potency. Gonadotropic fractions may not be free from thyrotropic effects.

Hypophyses of different species do not contain the same amount of each hormone. Thus identical methods of extraction when applied to the glands of different species will yield grossly different products. Even when glands of a single species are employed standardization is imperfect and it is probable that all available preparations have wide variations in potency.

Antagonism and synergism between different pituitary hormones have been insufficiently studied but are probably of importance. Thus there is considerable evidence that growth and gonadotropic hormones are to some extent antagonistic in such a way that an excess of growth stimulus may inhibit sexual development, an effect evident in the genital hypoplasia of prepubertal gigantism and in acromegaly and also perhaps in the slowing of growth which occurs with rapid sexual development at puberty. It has also been shown that fractions prepared with the idea of eliminating all influences except the growth stimulus have actually less potency in promoting growth than others which are less purified. Recently it has been demonstrated that both thyrotropic and galactagogue hormones either possess separate growth-promoting effects or else act as synergists to a hypothetical pure growth hormone.

Collip's demonstration of the so-called "antihormonal" effect which develops with the continued use of many pituitary preparations introduces another practical difficulty in therapeutic application. The nature of this phenomenon is still in dispute, present evidence indicating that it may be due to a reaction from the protein contained in most pituitary extracts rather than to the development of a true antihormone. Whatever may be its explanation, the fact remains that with many of the preparations now available, the initial and desired effect is later neutralized or reversed by continued treatment.

The effect of extracts varies widely in different species and

The effect of extracts varies widely in different species and

per cent, phosphorus 4.3 mg. per cent. A sugar tolerance test was normal.

The state of pituitary cachexia which follows destruction or ablation of the anterior lobe of the hypophysis was first described in man by Simmonds. It is regularly accompanied by a secondary atrophy of the genitals, the thyroid and adrenals and to a somewhat less degree by wasting of all tissues of the body. Clinically it is characterized by undernutrition, muscular atrophy, hypoplasia of the genitals, amenorrhea, a basal metabolic rate at the myxedematous level, and by low blood pressure and easy fatigue, features which have been attributed to adrenal insufficiency.

Although cases of complete destruction of the anterior lobe of the hypophysis are rare, many patients are encountered who present several of the symptoms of Simmonds' disease to a more or less striking degree and who must be considered as possible examples of pituitary insufficiency.

In the case of the girl who has just been presented, the criteria for positive diagnosis are not well established. Amenorrhea brought her to the clinic. Examination revealed moderate emaciation, easy fatigue, hypotension, a low basal metabolism, hypoplasia of the genitals. In the absence of chronic infection or other serious organic abnormality, the diagnosis of pituitary insufficiency may be justified.

From the circumstances of the case it may be inferred that the pituitary insufficiency was not apparent during childhood or at puberty and also that at the time of our observation it was not complete.

The girl was of normal height, the breasts while small had developed normally, the hair of the body had appeared in the normal female distribution. The menses had started rather late but appeared to be normal for eighteen months.

The weakness was not so extreme as to prevent ordinary occupation. A persistent cycle of uterine changes was indicated by the recurrent periodic cramps. The blood pressure while low did not reach those levels which frequently cause incapacity in complete pituitary cachexia. There was

duce demonstrable effects in amounts sufficiently small to be clinically practical. At least one available extract contains thyrotropic principle in amounts sufficient to produce measurable and at times striking changes in the metabolic rate. Several pituitary preparations have a sex-stimulating effect in monkeys and if judged from preliminary and somewhat meager clinical observations appear to produce similar changes in women. It would appear that these might be helpful in states of pituitary insufficiency particularly in those cases in which hypofunction of the thyroid with low basal metabolic rate and in those in which sexual infantilism are found to exist.

The circumstances of the following case give a fair example of the difficulties in diagnosis and in treatment.

Case I.—G. W., an unmarried woman of twenty-seven, was first seen in the Washington University clinics in June, 1935. She complained of amenorrhea for seven years and stated that for about two years she had suffered from easy fatigue. In spite of this she was able to keep her position as a dictaphone operator and to aid materially in the support of her family. As a child she had had only measles and chicken-pox. Her menses had started at the age of fifteen, were regular for the first eighteen months, gradually became irregular and scanty and stopped completely when she was twenty. Following their cessation, she had periodically each month headaches and abdominal cramps. At times but not regularly she noted some secretion from her breasts. She had never experienced any sexual desire.

Physical examination revealed a somewhat malnourished girl, 65 inches in height and weighing 104 pounds. Her skin was smooth and only moderately wrinkled. The axillary hair was sparse, the pubic hair normal. Her breasts were small but had a normal amount of glandular tissue. The systolic blood pressure was 95, the diastolic 65. Gynecological examination showed an infantile uterus with small adnexa. The basal metabolic rate was -21 per cent. *x*-Ray of the skull revealed a normal sella turcica. Serum calcium was 11.2 mg.

This pituitary preparation is known through the studies of Thompson¹ to possess among other properties a thyrotropic action in man and will in most cases cause a demonstrable effect upon the basal metabolic rate. For four weeks she received daily doses of 2 cc. The effect is best judged by reference to the table. The first notable action was a rise in basal metabolic rate followed after a brief interval by a definite fall to values well below those which preceded treat-

Fig. 23—Case I showing the myxedematous puffiness of the face which appeared for the first time following the administration of a pituitary extract possessing thyrotropic qualities.

ment. This secondary effect was not unexpected, had been noted repeatedly by others and should be considered an example of the so-called "antihormonal" effect.

It was remarkable in this case that during the period of falling basal rate, the patient acquired for the first time the appearance of myxedema with increased dryness of the skin, swelling of the face and marked puffiness under the eyes. Curiously these changes in appearance and in basal were re-

no history of sudden weakness with gastro-intestinal symptoms, an occasional feature of Simmonds' disease which simulates closely the addisonian crisis.

Many of the symptoms of this case, low basal rate, low blood pressure, amenorrhea, and weakness are observed in uncomplicated hypothyroidism. Although this was not thought to be the correct diagnosis, she was given 0.06 Gm. of thyroid daily from August 1 to September 5, 1935, and 0.03 Gm. until September 10. The effect of this treatment was to produce elevation of the basal with slight increase in blood pressure but without causing return of the menses and without subsidence of fatigue.

Immediately after discontinuance of thyroid medication her basal dropped again as may be seen in the accompanying table. In October, 1935, treatment with *phyone** was started.

TABLE 1
EFFECT OF TREATMENT UPON WEIGHT, BASAL METABOLISM AND BLOOD PRESSURE IN CASE I

Date	Weight	Basals	B.P.	Remarks
July 25, '35	104	-21		
Aug. 1	105	-18	90/55	Thyroid 1 grain started
Aug. 15	108	-4		
Sept. 5	109	+14	100/60	Thyroid $\frac{1}{2}$ grain

* Phyone was supplied to us through the courtesy of Dr. David Klein of the Wilson Laboratories, Chicago, Ill.

tumors of the eosinophile cells of the anterior lobes and giving rise either to prepubertal gigantism or acromegaly; the second, pituitary basophilism, recently emphasized by Cushing as an accompaniment of the relatively rare tumors of basophile cells. Tumors of the chromophobe cells of the hypophysis, clinically more numerous, produce no recognizable endocrine disturbance. Although it is not unlikely that states of hyperpituitarism result from physiological overactivity of cells without tumor formation, the contention is not at present susceptible to clinical or pathological proof.

Treatment of hyperpituitarism is limited at the moment to surgical removal of the tumor or to irradiation of the pituitary region. In acromegaly, operations have frequently been necessary because of the size of the tumor and its pressure upon the optic nerves or other neighboring structures. In many instances, such treatment has been successful in preventing further advance in the deformities of the disease.

In most cases of pituitary basophilism the tumor has been small. In only one instance has such a tumor been removed by operation. This was in the case reported by Lissner² at the meeting of the Association for the Study of Internal Secretions in 1936. In his patient were found characteristic changes of the syndrome described by Cushing. Operation was performed and a tumor having indifferent staining qualities and apparently arising from the pars intermedia of the gland was removed. Immediately improvement followed with regression of the prominent features of the disease for a period of two years.

While in acromegaly and possibly in cases of pituitary basophilism, it is possible to stay the progress of the condition by surgical means, the dangers of the operation are considerable. Furthermore, the approach is difficult and the tumor cannot often be sharply separated from the gland in which it is imbedded. As a result, the hypophysis itself has in many instances been destroyed with subsequent development of pituitary cachexia. Such considerations emphasize the hope of other forms of therapy.

accompanied by any variation in her subjective feelings. The last injection of *phyone* was given in November and was accompanied by a rather severe local reaction. Following its discontinuance, there was an elevation of the basal metabolic rate to levels approximately those observed before *phyone* was given.

In January, 1936, it was decided to try the effect of *prephysin*, a preparation of the Chappell Laboratories, said, on the basis of extensive laboratory investigation, to contain relatively large amounts of the gonadotropic hormone of the hypophysis. One cc. of this substance was given subcutaneously for six successive days. Again the basal metabolic rate fell but there were no other evidences of effect. The same course of treatment with *prephysin* was repeated in March, 1935, but was also without effect. Examination revealed no change in the size of the uterus. Menses were not induced although the patient continued to note the periodic return of cramps and headaches each month.

In this case, two pituitary extracts were employed. Each was prepared under excellent auspices; each had been found to have predictable actions in laboratory animals. The first preparation, *phyone*, produced notable but unfavorable changes; the second had no demonstrable effect, except a fall in the basal metabolic rate which from previous laboratory tests was not expected.

This experience does not necessarily imply that the extracts were clinically worthless. It does not preclude the cautious trial of these and other carefully prepared pituitary products. It illustrates a few of the difficulties which at the present time are inevitably encountered whenever the treatment of hypophyseal insufficiency is undertaken. It indicates the necessity of great numbers of careful clinical observations on the newer and well-tested laboratory products.

HYPERPITUITARISM

Overactivity of the pituitary gland finds clinical expression chiefly in two forms: the first, associated regularly with

large: 3 of his brothers being over 6 feet tall and weighing 200 pounds. He was small until the age of fourteen or fifteen, when he measured about 65 inches and weighed 125 to 130 pounds. At the time of administration his weight was 218 pounds and he was 74 inches tall. He had noted some growth in the size of his head in the preceding two years, and also a change in his facial expression. There was no loss of weight, no failure of libido, no disturbance of vision. At the time of entry he wore size 11 shoes. Three years before he had worn size 9.

Physical examination showed a man of large stature, with the heavy frame, large feet and spadelike hands. His face was large, the nose enormous, the eyes deep-set with large frontal prominences. He had marked mandibular prognathism. The general examination revealed no abnormalities. Laboratory studies showed a normal urine, normal blood count and negative Kahn. The glucose tolerance test was of diabetic type. The basal metabolic rate was plus 3. *x*-Ray of the skull showed a greatly enlarged sella turcica especially in the anterior posterior diameter. The neurological examination was entirely negative. Visual fields and ocular fundi were normal.

On December 3 and 4, 1934, he received two *x*-ray treatments directly over the pituitary region. This produced no unfavorable reaction and caused abrupt cessation of his headaches. On January 17, 1935, he received a second course of deep *x*-ray therapy. By March, 1935, his headaches had returned, although they were not so severe as those he had experienced before treatment. The third course of two *x*-ray treatments was given on March 4 and 5, 1935. Because his headache was little influenced by the third course he had a fourth treatment on June 12 and 14. This time he had a rather severe reaction to the *x*-ray.

Since headaches of variable severity continued during the summer he was admitted in September to the hospital with the idea that operation might be necessary. With bed rest he

As early as 1909, Granezma³ of Turin reported the case of a woman forty-five years of age who suffered from the severe headaches of acromegaly. By irradiation with x-ray he was able twice in eight months to cause the headaches to disappear. Unfortunately he was unable to save the life of his patient.

Detailed study of the effects of x-ray may be said to have started with the work of Beclere,⁴ who reported his first experiences in 1913. Especially significant was his account of an acromegalic girl with severe headaches, dizziness, vomiting and serious visual disturbances. She showed some evidences of gigantism as well as sexual infantilism. Improvement of her subjective symptoms started within fourteen days of the first irradiation. One year later the headaches and dizziness had entirely disappeared and the visual disturbances, of which Beclere made careful observations, had improved. Since that time many observations have been made on this form of therapy. An idea of their extent may be obtained from the report of Pfahler⁵ who in 1931 was able to find that good results from the roentgenological treatment of pituitary tumors had been reported by at least 77 authors. Recent reports of significance have been made by Pfahler⁶ on the careful study of 21 cases of pituitary tumor, 9 of which were acromegalic, and by Perémy⁷ who assembled 97 cases, of which 35 were acromegalic. At present it is the consensus that irradiation of eosinophilic tumors of the hypophysis offers definite hope of improvement. The results in the literature indicate a wide variation in effect, a part of which may be explained by differences in technic and a part possibly to differences in the resistance of tumor cells.

Case II.—H. S., a farmer, twenty-one years of age, was admitted to Barnes Hospital November 26, 1934. For nine months he had suffered from occipital headaches radiating to the temporal regions. For a month he had noted nocturia and frequency of urination.

He gave the history that all members of his family were

means at our disposal in the treatment of states of hyperpituitarism it must be emphasized that neither represents an ideal form of therapy. Some interest attaches to recent experiments, particularly those of Barnes¹⁴ and of Nelson¹⁵ who advance evidence that an excess of ovarian hormone may cause temporary arrest of at least one of the functions of the gland. The influence of the hypophysis upon other glands of internal secretion has been established by numerous investigations in the past few years. More recently, the effect of other glands upon the activity of the pituitary has become increasingly evident. The hope, therefore, may be entertained that, eventually, hyperfunction of the hypophysis can be influenced by factors other than removal or destruction of tumors.

SUMMARY

There is great need for clinical study of the treatment of diseases of the hypophysis. Although in states of pituitary insufficiency, replacement therapy should be effective, the present use of extracts is surrounded with many difficulties. Experience in laboratory animals cannot be applied directly to man and advance in therapy can come only from meticulous clinical observations under well-controlled conditions.

Hyperpituitarism in its recognized forms of gigantism, acromegaly and pituitary basophilism can in many instances be controlled either by operation or irradiation.

became so much more comfortable that operation was deferred.

In December he was seen again suffering from headaches of maximum severity. Advice for further x -ray treatment was not followed, but in May, 1936, the headaches had disappeared completely.

It is particularly notable that from the time of the first treatment there was no demonstrable advance in the acromegalic deformities.

The results of treatment in this case while not dramatic confirm the impression of many observers that irradiation may be helpful in controlling symptoms and in staying the progress of the disease. That the effect of x -ray should be tried in all acromegalic patients whose vision is not immediately threatened seems evident.

Experience with irradiation in cases of pituitary basophilism has been extremely limited.^{8, 9, 11} The improvement observed in a few might lead to the hope that basophile cells are more vulnerable to the x -ray than are the cells of eosinophile tumors. Particularly notable was the result obtained in a case originally observed by Cushing¹⁰ and reported this year by Aub¹¹ at the Association of American Physicians. Following irradiation this patient showed immediate and dramatic improvement with eventual complete regression of symptoms and return to normal configuration.

Accumulating evidence indicates that symptoms clinically indistinguishable from pituitary basophilism accompany and apparently may be produced by adrenal tumors. In a few of these cases careful serial sections of the hypophysis at autopsy have revealed no abnormality. In the individual case observed clinically the possibility of adrenal disease must always be considered. At present, it is not demonstrated that irradiation of the pituitary would be beneficial under such conditions. It is, therefore, not surprising to find in the literature cases of Cushing's syndrome in which no helpful effect from x -ray was obtained.^{12, 13}

While at present operation and irradiation are the only

CLINIC OF DR. LOUIS F. AITKEN

BARNES HOSPITAL

DIAGNOSIS AND TREATMENT OF HYPERINSULINISM

HYPERINSULINISM may be defined as a condition in which repeated hypoglycemic attacks result from the production of insulin in excess of the physiological needs. Although Harris¹ introduced the term only two years after the discovery of insulin² it was not until 1927 that Wilder³ first described the clinical condition. He reported the case of a physician who had a carcinoma of the islet tissue of the pancreas with metastatic growths in the liver. In the nine years that have elapsed since Wilder's report the literature has become voluminous.⁴ Many cases have been recorded and the dramatic results which may be obtained from correct diagnosis and operative removal of a tumor of the islands of Langerhans have been well established.

The following case illustrates many of the features by which the diagnosis may be determined and also indicates some of the problems that have arisen in the study of this fascinating condition.

Case Report.—E. M., a married woman of forty-four, entered Barnes Hospital on June 19, 1933. Her illness began in the summer of 1929 at which time there were symptoms of nervousness and attacks of confusion, amnesia, automatism and unconsciousness occurring before breakfast, and quite similar to attacks later identified as hypoglycemic in origin. In August, 1929, she was said to have had a classical picture of Graves' disease with a basal metabolic rate of $+80$ per cent. After preparation with iodine and quinine a subtotal

one to two minutes by intravenous administration. Fasting true blood sugar values of 10, 22, 34, 29, and 15 mg. per cent were noted at various times during her study. A sugar tolerance test of 1.75 Gm. of glucose per kilogram of body weight gave the following results:

Fasting sugar	10 mg. per cent
$\frac{1}{2}$ hour	106 " " "
1 "	179 " " "
2 hours	248 " " "
3 "	228 " " "
4 "	124 " " "
5 "	60 " " "
6 "	39 " " "
7 "	37 " " "
8 "	45 " " "
9 "	47 " " "

During the fourth hour of the test she developed a severe headache and hunger followed by vomiting. During the fifth hour she became confused and her facial expression was blank and staring. She responded to questions and commands, but had complete lapse of memory for all events which followed the headache and vomiting.

On a carbohydrate intake of 150 Gm. supplemented by 200 cc. of orange juice at 3 A. M., the following blood sugar values were obtained: 6 P. M., 72; 9 P. M., 34; 12 M., 43; 3 A. M., 24; 6 A. M., 42; 9 A. M., 81; 12 M., 55; 3 P. M., 83; 6 P. M., 84. The blood amylase test was normal by Somogyi technic. Basal metabolic rate was -6 per cent. The blood Kahn was negative. Stereo of skull and other laboratory findings were within normal limits.

At the time this patient was being studied, the work of Houssay, Barnes⁵ and others had shown that many extracts of the pituitary gland contain a diabetogenic principle which tends under some conditions to raise the level of blood sugar. A study of the effect of such an extract on a patient with hyperinsulinism appeared to be of some interest. She was given therefore a pituitary fraction, Q 40, which was furnished to us by Dr. J. B. Collip. This was administered in doses of

thyroidectomy was performed. Except for a gain in weight her convalescence was uneventful. Previously noted fibroids were satisfactorily removed in April, 1930. By June of that year she had again developed attacks of confusion, weakness, clumsiness, and at times unconsciousness and convulsions.

Milder manifestations were a sense of inward nervousness, at times hunger, mental confusion, disorientation, purposeless or athetoid movements, muscular twitchings, and repetition and thickness of speech. There were many phases of prolonged amnesia and automatism. During one such attack she telephoned a physician, admitted him to her household, and then proceeded to roll violently across the floor from one side of the room to the other. A sharp command arrested the activity so dramatically that a diagnosis of hysteria was made. In March of 1933 after a prolonged series of convulsions a right-sided hemiplegia developed. She remained unconscious and hemiplegia persisted for four days in spite of generous amounts of intravenous glucose. With return of consciousness the hemiplegia disappeared. Blood sugar studies and a five-hour sugar tolerance revealed a diabetic curve without hypoglycemia. The attacks gradually became more frequent and increasingly severe. Characteristically they would develop after a prolonged fast or following unusual physical exercise.

Her husband learned early in the course of the patient's illness that sweetened milk would alleviate mild attacks and abort an attack of unconsciousness. In June, 1933, attacks were frequent and severe. She herself learned that if she would eat a hot dog sandwich and drink a bottle of beer at midnight, she could avoid a convulsion the following morning.

Physical examination revealed obesity, a coarseness of features with some lack of expression; a moderate hypertension, 150/90, and the scars of thyroidectomy and hysterectomy. The neurological examination was entirely negative. During hospitalization in June, 1933, many attacks were observed. Prompt relief of symptoms could be induced in fifteen to twenty minutes by ingestion of carbohydrate, and in

consistency, attached to pancreatic tissue. It appeared to be partially encapsulated. Sagittal section disclosed a necrotic area, 4×3 mm., eccentrically placed. The tumor was divided into small pieces for fixation in aqueous chrome sublimate and modifications of the same containing 10 per cent formalin and 5 per cent acetic acid respectively, Bouien's and Altmann's fluids, and 10 per cent formalin in 90 per cent alcohol. Bits were also placed in Ringer's fluid and in 1:2000 neutral red in normal saline for examination in the fresh state.

The fresh material did not tease readily and cells for study were obtained with difficulty. These were examined with the oil immersion lens. Their cytoplasm showing a haze of tiny granules characteristic of the cells of normal islets of the pancreas, and a variable content of refractile globules suggesting lipoid. The nuclei were large, clear and contained a prominent nucleolus. In the fresh material previously immersed in neutral red, the granules of occasional cells stained with the dye, those of the majority, even when adjacent to cells with colored granules, remained unstained. In the cells of normal islets under similar conditions, the specific cytoplasmic granules color with the dye. Macrophages, mast cells and lymphocytes in considerable numbers were observed in addition to the cells heretofore described.

The fixed material, after dehydration and embedding, was sectioned in paraffin at 4 microns and stained with Heidenhain's azocarmine modification of Mallory's connective tissue stain, Bensley's and Bowie's neutral stains, and hematoxylin and eosin.

Figure 24, *a* and *b*, are low-power photomicrographs of areas of the formol chrome sublimate block of the tumor stained with hematoxylin and eosin and the modified Mallory stain respectively. Examination of these sections revealed that the tumor was composed of cords and irregular masses of cells closely akin to the cells found in normal islets of the attached pancreas. In places, the tumor tissue encroached upon normal pancreas (Fig. 24, *b*): and lobules of acinar tissue were observed to project into the tumor and cords of tumor cells across

2 cc. every three hours for twenty-four hours. A sugar tolerance test following the last injection failed to show any appreciable change in the character of the curve. It may be mentioned in passing that the conditions of this trial were not favorable, that the potency of the fraction in diabetogenic principle was not definitely known and that the duration of administration may not have been sufficient. This observation does not preclude the possibility that other extracts with greater diabetogenic action given under other conditions might not have a demonstrable effect. At the time the condition of the patient did not permit further observation of this type of therapy.

On June 29, 1933, following the administration of 500 cc. of intravenous glucose, Dr. A. O. Fisher using avertin and nitrous oxide anesthesia explored the region of the pancreas. The abdomen was opened through a left paramedian incision. There was a very thick layer of fat in the abdominal wall. The rectus was retracted laterally, the peritoneum was opened and the gastrocolic omentum was incised, affording a rather good exposure of the pancreas which lay deep in the wound. The posterior parietal peritoneum was incised over the pancreas and it was possible to palpate the latter throughout its entire length and even to the head. Nothing was made out on inspection, but about the middle of the body of the pancreas a firm well-defined area quite different from the normal pancreas was felt. Assuming that this area contained the tumor, it was removed, taking a wedge-shaped portion of pancreas. After removal it appeared to be more like an isolated island of firm tissue. There was considerable troublesome bleeding which was carefully controlled. The cut edges of the pancreas were approximated with interrupted sutures. The field was left quite dry and a Penrose drain was brought from this region through a stab wound in the left side.

Dr. James O'Leary examined the tumor and made the following histological study:

Inspection of the material revealed a small ovoid tumor. 13 × 6 mm. in size, yellowish gray in color, of firm elastic

consistency, attached to pancreatic tissue. It appeared to be partially encapsulated. Sagittal section disclosed a necrotic area, 4×3 mm., eccentrically placed. The tumor was divided into small pieces for fixation in aqueous chrome sublimate and modifications of the same containing 10 per cent formalin and 5 per cent acetic acid respectively, Bouien's and Altmann's fluids, and 10 per cent formalin in 90 per cent alcohol. Bits were also placed in Ringer's fluid and in 1:2000 neutral red in normal saline for examination in the fresh state.

The fresh material did not tease readily and cells for study were obtained with difficulty. These were examined with the oil immersion lens. Their cytoplasm showing a haze of tiny granules characteristic of the cells of normal islets of the pancreas, and a variable content of refractile globules suggesting lipid. The nuclei were large, clear and contained a prominent nucleolus. In the fresh material previously immersed in neutral red, the granules of occasional cells stained with the dye, those of the majority, even when adjacent to cells with colored granules, remained unstained. In the cells of normal islets under similar conditions, the specific cytoplasmic granules color with the dye. Macrophages, mast cells and lymphocytes in considerable numbers were observed in addition to the cells heretofore described.

The fixed material, after dehydration and embedding, was sectioned in paraffin at 4 microns and stained with Heidenhain's azocarmine modification of Mallory's connective tissue stain, Bensley's and Bowie's neutral stains, and hematoxylin and eosin.

Figure 24, *a* and *b*, are low-power photomicrographs of areas of the formol chrome sublimate block of the tumor stained with hematoxylin and eosin and the modified Mallory stain respectively. the boundary into acinar tissue. In other areas the normal pancreatic and the tumor tissue were separated by a mass of

somewhat hyalinized connective tissue containing ducts, ducts apparently differentiating into tumor cells (Fig. 25), and lobules of acinar tissue.

The larger area of the tumor was representative of the early and intermediate stages of Bensley's chronological classification of islet cell adenomata (Womack, Graham and Gnagi, 1931).⁶ The cords and small masses of tumor cells were separated by capillary vessels of varying width. The amount of connective tissue about these varied from very slight to a

Fig. 25.—High-power photomicrograph of a zone centrally situated in the tumor illustrating the differentiation of a duct into adenomatous cells and a typical group of islet tumor cells. *D*, Duct; *Ad*, adenomatous tissue.

small amount. In a few small areas, an approximation of the older stage of Bensley's classification, in which cords of islet tissue were separated by strands of hyalinized connective tissue was observed.

The tumor cells were on the whole slightly larger than the normal islet cells in the adjoining pancreas; but the same shape variations were evident (Fig. 26). In large areas the majority of cells appeared healthy, few pyknotic nuclei being observed; in other areas pyknotic nuclei were much more frequent, the cytoplasm of many cells was pale (H. and E.). In

the latter cells characteristic cytoplasmic granulations were absent and cell boundaries not distinct.

The staining reactions of the majority of healthy tumor cells resembled those of the beta variety of normal islet cells (control: islets of adjoining pancreas), but differences were evident. After formol chrome sublimate fixation, the specific granules in the beta cells of normal islets colored faint blue with the modified Mallory stain; the tumor cell granules which varied somewhat in size, colored a dull lilac. Whereas in normal islet beta cells the cytoplasm in which the granules

Fig. 26.—High-power photomicrograph illustrating the occurrence of degenerative cells in an area still containing healthy cells.

were embedded failed to stain, in the tumor cells it colored the same as the granules but less intensely. Material fixed in aqueous and acetic chrome sublimates gave similar deviations in the staining reactions between normal islet beta cells and the cells of the tumor. A small minority of healthy appearing cells in the tumor (formol chrome sublimate) had specific cytoplasmic granules which, like those of the β cells of normal islets of the pancreas, colored an intense blue with Bensley's neutral gentian. These may represent true β cells.

Other differences were apparent between the islet and the

tumor cells. Many tumor cells possess the characteristic cytoplasmic inclusions of varying shape and staining bright red with the modified Mallory stain. These have been observed in variable numbers in each of the other four tumors⁷ of similar nature removed at Barnes Hospital. They have not been found in normal islet cells. An occasional cell occurred in the tumor, the cytoplasm of which was loaded with vacuoles of uniform size; these cells are to be distinguished from cells bearing one or more small vacuoles which occur in normal islet and in tumor islet tissue alike.

The similarity in size of the cytoplasmic granules of tumor islet cells and those of argentaffine cells of the gastro-intestinal tract, which may also form tumors, make it necessary to rule out the latter. This was accomplished by a specific staining reaction for the granules of argentaffine cells discovered by Masson (1928).⁸ The granules of the tumor cells did not stain with the silver, whereas excellent stained granules were obtained in the argentaffine cells of a control section of intestine.

The paucity of mitotic figures and high degree of differentiation of the component cells of the tumor discounts malignancy and, with the other evidence presented, places the tumor as a modified β cell adenoma of the pancreas.

Postoperatively there was a temporary period of diabetic state with fasting sugars of 248 to 255.

A sugar tolerance test fifteen days following operation was as follows: fasting, 85; half hour, 215; two hours, 218; three hours, 218; four hours, 164; five hours, 109. Subsequent to the operation the patient developed a pancreatic cyst which required drainage and marsupialization.

Gradually the patient developed symptoms of hypothyroidism with a basal of —18 per cent, and now requires $1\frac{1}{2}$ to 2 grains of desiccated thyroid per day. At no time has there been any evidence of return of hypoglycemia.

Discussion.—The case illustrates many typical features of hyperinsulinism secondary to an islet cell adenoma of pan-

creas and cured by successful removal of tumor. Repeated blood sugar observations during various attacks revealed there was no direct relationship between sugar level and the severity of the symptoms. The persistent unconsciousness and hemiplegia for four days, even though generous amounts of glucose were administered and blood sugar remained at normal and hyperglycemic levels, occurred after a rather prolonged and severe attack of hypoglycemia before sugar was administered. This case as many others had been considered as hysteria, epilepsy and encephalitis.

Symptomatology of Hyperinsulinism.—The diagnosis of hyperinsulinism depends on the demonstration of chronic hypoglycemia dependent upon an overactivity of the island cells of the pancreas. The history of the attacks and the symptoms produced are in no way different from an overdose of insulin such as one might encounter in the treatment of diabetes mellitus. The disease is usually insidious, attacks being at first mild and occasional, later becoming more frequent and more severe. The mild attacks may be described as a feeling of weakness, hunger and nervousness. Instead of hunger the patient may complain of a feeling of heaviness in abdomen, nausea, or a rather pronounced epigastric pain. Early in the attack there is loss in ability to concentrate. The patient may feel light-headed and giddy. Emotional instability may become manifest. This may be followed by manifestations of hyperadrenalemia. The pulse becomes quickened, there is tremor of fingers and hands, blood pressure is elevated and profuse sweating ensues. Weil^o calls particular attention to the finding of a circumoral pallor occurring early in the attack. If the degree of hypoglycemia progresses further there is usually some mental confusion. The patient may show long periods of amnesia and automatism. This state has often led to such erroneous diagnoses as hysteria. The patient may be hyperexcitable during this stage and undergo extremely vigorous efforts, very often with a feeling of attempting to escape from some fear or injury. Convulsions either of jacksonian or general type are frequent and

indistinguishable from true epileptiform seizures. Following the hyperanxiety state and overactivity or convulsive seizure there usually develops a feeling of drowsiness and tendency to fall asleep.

During hypoglycemia there is a deficiency of sugar supplied to the brain. With such deprivation the patient may develop symptoms of diplopia, scotomata, hemiparesis or hemiplegia or a true epileptiform convulsion. It is significant that in prolonged attacks of hypoglycemia, the restoration of the blood sugar level is not always followed immediately by a disappearance of the neurological manifestations. The latter may require several hours or days to return to normal. Although the intelligence quotient has been reported as dramatically improved by the total relief of hyperinsulinism,⁴³ some cases show marked residual mental deterioration. Those cases in which fatalities resulted in spite of adequate administration of glucose are possibly due to so prolonged a malnutrition of brain tissue as to prevent recovery and repair. Joslin¹⁰ reports this same observation in association with huge overdoses of insulin in diabetic patients.

Such neurological manifestations aborted or relieved by adequate administration of carbohydrate is more than presumptive evidence of hypoglycemia. The attacks characteristically occur after a long fast or missing of a meal. Metabolic processes which accentuate depression of blood sugar level or stimulate normal insulin production such as vigorous physical exercise are apt to provoke an attack.

Blood Sugar Studies.—Confirmatory evidence is the finding of a low blood sugar during a seizure with prompt relief of symptoms by the administration of carbohydrate. Although a long fast may provoke an attack, fasting blood sugar values in proved cases have been found to be normal or even elevated. The sugar tolerance test is of distinct value as a diagnostic aid. The usual amount of sugar recommended is 1.75 Gm. per kilogram of body weight. Blood samples for sugar content are taken at half-hour, one-hour, two-hour, three-hour, four-hour, and five-hour intervals. The conven-

tional three-hour sugar tolerance test may fail to deviate from the normal or may actually simulate a diabetic type of curve. The marked fall in blood sugar level may be evident only in the fourth or fifth hour.

Differentiation from Other States of Hypoglycemia.

—As has been emphasized the main symptoms associated with hyperinsulinism are those of hypoglycemia, which like the opposite condition of elevated blood sugar, may arise from any one of several factors controlling the storage and utilization of carbohydrate. A loss of glycogen stores secondary to extensive disease of the liver such as carcinoma,¹¹ acute yellow atrophy,¹² and excess fatty infiltration of the liver¹³ has been identified as a cause of hypoglycemia. Scheiman¹⁴ in a study of 6 cases of progressive muscular atrophy reported 2 cases of hypoglycemia. A depletion of the glycogen reserves sufficient to produce very low levels of blood sugar has been observed in malnutrition,¹⁵ in renal diabetes,¹⁶ in lactation,¹⁷ and in prolonged muscular exercise.¹⁸

Hypoglycemic reaction resulting from increased vagotonia was reported in 1926 by J. M. Nielsen.¹⁹ Ryneerson²⁰ later reported 2 cases in which there was hypoglycemia associated with vagotonia which was interpreted as being secondary to psychiatric disturbances influencing the blood sugar regulating center in the pons. The antithesis of this blood sugar regulating effect is clearly demonstrated in the case of de Takáts and Fenn²¹ in which the diabetic state of a boy with Graves' disease was much improved following thyroidectomy. His diabetes continued to be rather difficult to control and was attributed to a persistent high degree of sympatheticotonia. There was a dramatic increase in sugar tolerance following a bilateral section of the splanchnic nerves.

The loss of control of blood sugar level resulting from altered function of the other glands of internal secretion may simulate true hyperinsulinism. Adrenal insufficiency, pituitary tumors and hypothyroidism have been associated with hypoglycemic convulsions. Some of the earliest reports of hypoglycemia were found in cases of Addison's disease.²²

Anderson²³ reports a case of fatal hypoglycemia in which a tumor of the adrenal gland was found. J. Wilder²⁴ reported a case of pituitary tumor with hypopituitarism in which severe hypoglycemic attacks were aborted only by adequate administration of carbohydrate. This has been interpreted as a loss of the diabetogenic substance of the hypophysis demonstrated by Houssay^{5, 25} and others. The rôle of this substance is further emphasized in the Houssay dogs where total ablation of the hypophysis is accompanied by an extreme sensitivity and hypoglycemic effect to relatively minute doses of insulin.

The association of hyperglycemia and glycosuria with thyrotoxicosis is well known.²⁶ Reduction of insulin requirements and increased carbohydrate tolerance following thyroidectomy in diabetes with Graves' disease has frequently been observed. The antithesis of this relationship is cited in Campbell's²⁷ cases of myxedema with hypoglycemia in which the level of blood sugar was stabilized by the administration of thyroid medication. Womack²⁸ resected a large portion of the pancreas in a patient with attacks of hypoglycemia associated with thyrotoxicosis in which the latter state spontaneously regressed following operation. He interprets the increased activity of the thyroid as a supplementary process of glycogen mobilization in response to the state of hypoglycemia. This result is significant in consideration of the case presented in this report. In the latter instance the hypoglycemic attacks were relieved during the state of thyrotoxicosis and returned following thyroidectomy. It is also significant that a state of hypothyroidism developed following relief of the hypoglycemia by resection of the adenoma.

Having established beyond doubt the presence of the syndrome of chronic hypoglycemia, extrapancreatic influences must be excluded. The factor of depleted glycogen stores is unlikely in the absence of any clinical evidence of marked liver or muscle disease. Test with epinephrine is useful since the hyperglycemia following its administration is dependent upon sufficient amount of glycogen in the liver. Unfortunately

it is not yet clinically possible to assay accurately the blood serum or urine for changes in quantity of the pituitary hormones. If there is any question of pituitary influence the sella turcica should be x-rayed and the patient should be most carefully observed for other evidences of pituitary dysfunction. Changes in thyroid secretion should be excluded as a possible primary or secondary contributing influence. Adrenal insufficiency must be excluded. Last but possibly not least, the factor of any fundamental disturbance of the vegetative nervous system must be investigated.

Although the type of sugar tolerance curve is not definitely diagnostic, it is worthy of note that the so-called "functional" case of chronic hypoglycemia tends to display a flat curve.²⁹ There seems to be more than a possibility that in some cases of functional hypoglycemia there exists a state of insulin hypersensitivity rather than a true overproduction of insulin. Further studies of insulin sensitivity in cases of chronic hypoglycemia have been suggested by MacBryde²⁹ as an important adjunct in the differentiation between true hyperinsulinism and functional chronic hypoglycemia.

Pathology.—The pathological lesions of hyperinsulinism may be classified into three groups. The first includes that of malignant degeneration of islet tissue of the pancreas with or without metastases.^{3, 44} In Wilder's case an analysis of the tumor tissue revealed a relatively high concentration of insulin-like substance. The second comprises those cases of adenoma or adenomata of islet tissue. It is this latter type of hyperinsulinism which offers the best prognosis of permanent effective cure. Terbrüggen³⁰ was the first to observe multiple adenomata in a thirty-year-old woman in which fatal hypoglycemia occurred. Both Graham³¹ and Whipple⁴ report a case unimproved following excision of adenomatous tumor, who were operated a second time with the finding of a second tumor nodule which on removal effected a clinical cure.

The sizes of the tumors reported vary from the size of a small pea to that of a grapefruit. As in other glandular

tumors such as the thyroid, the severity of the symptoms bears no relationship to the size of the tumor but varies directly with the degree of secretory activity of the beta type cell. The tumors are usually found in the body or tail of the pancreas where islet tissue is normally more abundant. The smaller tumors were of a purplish-red color because of their high vascular character. The larger tumors contained areas of necrosis and were more yellow in appearance. In the baseball tumor of Graham³¹ the degenerative process was accompanied by calcification. The tumors were not always encapsulated. In a pathological study of 5 cases of hyperinsulinism with adenomata by O'Leary⁷ the case presented in this report was considered as a transition tumor type. In some portions of the tumor there was definite encapsulation. In other areas there was no capsule and the histological picture was typical of a simple hyperplasia and hypertrophy of islet tissue.

The final analysis of a given case should include an accurate histological study of the cellular elements making up the tumor. Bensley⁷ and his coworkers have elaborated a study of both normal pancreas and of pancreatic tumors in which an accurate differentiation of the cellular elements can be determined. This cellular study includes examination of the fresh tissue suspended in Ringer's fluid and in 1:2000 neutral red in normal saline solution for granules and lipid content as well as special staining qualities of the fixed tissue. In those cases in which such studies were carried out, the beta type cell definitely dominated the active portion of the tumor structure.

In the third group of cases there is a diffuse simple hyperplasia and hypertrophy of the islands of Langerhans. Such cases have developed from excess stimulation of islet tissue by large and frequent carbohydrate intake or prolonged hyperglycemia. Hartman³² observed the case of a child who was seized with convulsions and coma following the sudden withdrawal of carbohydrate by a stern mother in her effort to preserve her winter supply of jams and jellies. The child

had been eating regularly huge amounts of jams and jellies in spite of ordinary discipline. Sudden withdrawal of this nutriment by placing a padlock on the refrigerator resulted in a severe state of hypoglycemia with convulsions. Gradual withdrawal of carbohydrate effected an uneventful recovery.

This same pancreatic response is duplicated in some reported cases of diabetes mellitus of long standing in which the chronic hyperglycemia stimulated the remaining islet tissue to hyperactivity and hyperplasia.³³ Some deaths in the newborn of diabetic mothers have been attributable to a state in which during intra-uterine life there is hyperplasia of islet tissue from constant hyperglycemia, and a secondary fatal hypoglycemia following birth and removal of the infant from the maternal influence.³⁴

De Takáts³⁵ produced hypertrophy of the islets of the pancreas by ligation of the pancreatic duct. This experimental finding was duplicated by Wilder's case in which a stone was found occluding the pancreatic duct associated with hypertrophy of the islet tissue.

Treatment.—*Medical.*—Some of the less severe cases of hypoglycemia attacks and possibly hyperinsulinism have been relieved by a high carbohydrate intake with frequent intermediary feedings. Such therapy, however, may lead to marked obesity and a progressively increased demand for sugar. A more satisfactory dietary treatment is that recommended by Clark and Greene³⁶ in which the depressing effect of insulin stimulation is utilized in the large fat ratio intake. Patients are placed on a diet of 60 Gm. of carbohydrate, 60 Gm. of protein, and 210 Gm. of fat. Weil's⁹ diet in so-called functional hyperinsulinism is more palatable and about equally successful. In this, 100 Gm. of carbohydrate, 60 Gm. of protein, and 250 Gm. of fat, were used.

John³⁷ has reasoned that just as excess carbohydrate may derange the mechanism of insulin production to the extent of clinical hyperinsulinism, the use of exogenous insulin given after meals before the blood sugar has an opportunity to stimulate the secretion of insulin would effect a physiologic

rest of the islet tissue. The application of this principle appeared to be effective in 3 cases. Patients were placed on a high fat diet in the proportions of 100 Gm. of carbohydrate, 80 Gm. of protein and 250 Gm. of fat. Ten to twenty units of insulin were given one-half hour after meals. After two and one-half to three months these patients were able to discontinue insulin and return to normal diet without apparent return of symptoms. It seems unlikely that such management would be effective in true hyperinsulinism from active tumors of the pancreas.

Surgical Treatment.—If a case can be accurately classified as hyperinsulinism of anatomic type, the treatment of choice is surgical. The operative mortality in technically good surgical hands⁴ is remarkably low. The finding of an adenoma of islet tissue type and its successful removal will eventuate in complete and dramatic cure, the only exception being the presence of multiple tumors or malignant degeneration with metastases in which entire removal of tumor tissue is technically impossible. A detailed description of surgical technic may be found in the following references.^{4, 35}

In the event that diffuse hyperplasia is found, subtotal pancreatectomy has afforded excellent results. Graham³⁹ resected 80 to 90 per cent of a pancreas in a one-year-old child suffering from severe hypoglycemic attacks with dramatic cure and no lasting evidence of pancreatic insufficiency. The early failures such as that of Finney⁴⁰ and those reported by Judd, Allan and Ryneerson,⁴¹ may have been more effective had a more generous removal been accomplished.

Treatment by Radiation.—The relief of hyperinsulinism by radiation as reported by Barrow⁴² has all the advantages and disadvantages of such therapy to other glandular tumors. The effectiveness in a given case is extremely difficult to evaluate and since the operative mortality is small, the possibility of overlooking an early carcinoma more than compensates for the surgical risk.

There is no doubt that the so-called "non-anatomic" or functional cases of chronic hypoglycemia are a direct chal-

lenge to the internist since the understanding of carbohydrate metabolism is far from complete and such palliative procedures as subtotal pancreatectomy should be regarded as unsatisfactory. On the contrary, prolonged but unsuccessful conservative treatment may not only prevent the possibility of curing an early carcinoma but also may allow irreparable injury and degeneration of the nervous system.

Summary.—1. Hyperinsulinism should be differentiated from other factors or diseases capable of producing chronic hypoglycemia. A comprehensive understanding of carbohydrate metabolism will in many instances avoid the necessity of subtotal pancreatectomy as a symptomatic cure. Exploratory laparotomy is not indicated unless the case is refractory to dietary treatment or shows rapid progression of frequency and severity of hypoglycemic attacks.

2. If carcinoma is present, prolonged conservative treatment may permit metastases to occur. Frequent and prolonged hypoglycemia retards mental development and is followed by mental deterioration.

3. Failure of relief of symptoms following removal of an adenoma may be due to existence of multiple tumors or malignant degeneration with metastases.

4. A case is presented in which an adenoma of beta cell type successfully removed produced a complete cure. The study of this case demonstrates the importance of extending the sugar tolerance test to five hours. Blood sugar determinations during various attacks revealed there was no direct relationship between sugar level and the severity of the symptoms. Blood sugar observations made after a prolonged attack of hypoglycemia were found to be within normal limits without alleviation of abnormal neurological state.

5. In this case, the development of Graves' disease following inception of attacks of hypoglycemia, the increased severity of hyperinsulinism following thyroidectomy, and the hypothyroid state following removal of adenoma of pancreas indicate a possible compensatory action of the thyroid gland in hypoglycemic states.

CLINIC OF DR. THEODORE C. HEMPELMANN

FROM THE DEPARTMENT OF PEDIATRICS, WASHINGTON UNIVERSITY SCHOOL OF MEDICINE AND THE ST. LOUIS CHILDREN'S HOSPITAL

ENCEPHALITIS: CLINICAL TYPES, THEIR SYMPTOMS, DIAGNOSIS AND TREATMENT

THE terms encephalitis and encephalomyelitis have appeared in the literature with increasing frequency in the last few years, but unfortunately under these names are included a wide variety of subjects entirely unrelated to each other. Accurate classification of such disorders is impossible until more is learned of their etiology and pathology, but for the purposes of this discussion, they have been grouped according to clinical manifestations as follows: (1) Toxic encephalitis—(a) idiopathic form, (b) encephalitis due to lead or arsenic; (2) epidemic encephalitis—(a) lethargic (von Economo) type, (b) Japanese "Type B," (c) Australian X disease, (d) St. Louis type of 1933; (3) acute disseminated encephalomyelitis associated with infections (postinfection encephalitis), including postvaccinal encephalitis; (4) unclassified types.

TOXIC ENCEPHALITIS

This term is frequently employed to designate any form of encephalitis not clearly of the epidemic type. It would probably be better, however, to limit its use to those cases of nonepidemic encephalitis not obviously associated with any of the specific infectious diseases. The etiology may be entirely obscure, or the condition may be produced by various drugs or chemicals, especially lead or arsenic.

ner and amount as a 20 per cent dextrose solution is commonly employed.

(b) **Encephalitis Due to Lead or Arsenic.**—This condition is much better understood than the preceding since it has long been known that both lead and arsenic when absorbed by the system even in small amounts but over a long period of time, are capable of producing toxic manifestations which may involve the nervous system. Lead, moreover, can be absorbed not only through the gastro-intestinal tract, but also through the lungs or skin in sufficient quantity to produce such symptoms. Indeed, instances are reported in which burning wooden storage battery plates, heavily impregnated with lead, have produced plumbism through inhalation of the fumes, and in children, eating paint from toys and cribs or even the use of nipple shields and dusting powders containing lead have produced such manifestations. In childhood, too, lead encephalitis seems to occur with much greater frequency than in adults, and is far more serious. That arsenic may prove to be an equally serious menace to the nervous system is attested by the fact that peripheral neuritis following its prolonged use has been recognized for many years, and encephalitis, as a sequel, has been brought to the fore especially since the use of the arsphenamine compounds in the therapy of syphilis and other conditions.

The pathology of lead encephalitis is especially striking: there is a marked increase in intracranial pressure due to intense cerebral edema, often accompanied by petechial hemorrhages, focal collections of cells, and degenerative changes in nerve cells. Injury to the central nervous system may be so great as to lead to residual spastic paralysis, epilepsy, blindness, tremors and mental deterioration.

Encephalitis due to *arsenic* is less common, but is occasionally seen especially in children receiving arsenical anti-luetic treatment. There is a greater tendency to hemorrhage, but less cerebral edema and fewer permanent residual manifestations.

Symptoms.—Following an indefinite period of anorexia,

(a) **Idiopathic Form.**—The disease appears to be commoner in children than in adults, but its etiology and the factors which are operative in its production are entirely unknown. Moreover, opportunities for careful studies of the pathology have not been numerous enough to warrant final classification, although rather common findings appear to be cerebral congestion and edema, petechial hemorrhages, especially in the gray matter, occasional areas of round cell infiltration and degeneration of nerve cells, but without evidence of demyelination.

Symptoms.—The onset is usually sudden, although occasionally it may be preceded by one or two days of malaise and even slight fever. The chief complaints are headache and nausea, followed in a few hours by marked drowsiness or convulsions. Fever rarely lasts more than a few days, and is occasionally absent. Meningeal symptoms, such as rigidity of the neck and positive Kernig or Brudzinski are not infrequently present at the onset, but rarely very pronounced or persistent. There may be paralysis of one or more extremities or of the face and eye muscles, but, as a rule, these are quite transient, disappearing completely within a few days. Changes in the knee jerks, or plantar and abdominal reflexes may be observed, but vary a great deal at different times in the same patient. The spinal fluid is clear, the pressure somewhat increased, and there is a moderate increase in globulin and mononuclear cells. The course of the disease is ordinarily a brief one, recovery occurring in the majority of cases within a few days to a week or two. Residual effects are uncommon, although mental deterioration and spastic paralysis is occasionally noted. The treatment is entirely symptomatic. Lumbar puncture may relieve the headache and even the convulsions, and theoretically, at least, the intravenous injection of hypertonic dextrose or saline solution, and especially 40 per cent sucrose (cane sugar) solution would appear to be advantageous in lessening the edema of the brain and possibly sparing the nerve cells a certain amount of damage. The sucrose solution may be used in the same man-

in lead colors, because of their well-known habit of putting such things in their mouths. Once plumbism occurs, removal of the lead (*i. e.*, by producing an alkalosis or acidosis, giving parathyroid hormone, reducing the amount of calcium ingested, etc.) is probably inadvisable, because of the danger of mobilizing the lead which may have been deposited in the bones, thus intensifying the symptoms. Since the metal is relatively inert when deposited in the bones, this should be encouraged by means of the administration of lime salts and alkaline phosphates, and perhaps adding vitamin D (viosterol, etc.) to the diet. Eventually, there is then the prospect of its gradual elimination through natural channels.

Since most of the acute symptoms may be accounted for by the intense cerebral edema, treatment of the acute phase consists largely in attempting to lessen this. Intravenous injections of hypertonic dextrose, saline or magnesium sulphate have been used for this purpose, but perhaps a better preparation would be 40 per cent sucrose (cane sugar) solution, which may be used intravenously in about the same dosage as 20 per cent dextrose solution. In addition, convulsions may require the use of sedatives. Unfortunately, treatment is rarely very effective.

EPIDEMIC ENCEPHALITIS

(a) **Lethargic (von Economo) Type.**—Although it seems probable that this disease was first noted many years ago, to von Economo belongs the credit of again calling attention to it, in a classical description of a Viennese epidemic in 1916. Since then it has been reported from practically all parts of the world.

Etiology and Pathology.—The cause is unknown, although it is usually considered to be one of the diseases due to a filtrable virus. Attempts have been made to establish a relationship between this disease and the virus of herpes simplex (fever blisters) and epidemic hiccup, but this claim has never been substantiated. Nor is the manner of its spread clear, although it is assumed that exposure to "carriers" or unrecognized cases of the disease are probable factors in its

constipation and abdominal cramps, the cerebral symptoms of plumbism develop. Briefly, these consist of a change in disposition, visual disturbances, including strabismus or ptosis, change in pulse rate and somnolence and convulsions. The increased intracranial pressure may lead to projectile vomiting, increased blood pressure and choked disks. The pressure indeed may be so great as to cause separation of the cranial sutures in children. Fever is usually absent, except in the terminal phases or when other infections are present. The spinal fluid is clear, the pressure greatly increased, and the globulin tests positive, although the cell count is either normal or shows a mild increase of lymphocytes.

When confronted with the possibility of encephalitis being due to plumbism, corroborative evidence of lead poisoning should be sought. Basophilic stippling of red cells is often present, as well as the bluish "lead line" at the edge of the gums (commoner in adults than children), and more important, the roentgenographic evidence which consists of an increased zone of density at the ends of the long bones beneath the epiphyseal line. Finally, the lead may be revealed by means of a spectroscopic examination of the blood and spinal fluid, or its quantitative estimation in the feces.

Prognosis.—This is always very serious, the mortality being highest in patients with convulsions, but being at least 25 per cent including all types of cases. Unfortunately, residual effects (blindness, paralysis, tremors, mental deterioration, etc.) are not uncommon even when the patient survives, and since the lead is often stored in the bones in apparently recovered cases, there is always the possibility of a recurrence of the cerebral symptoms through the mobilization of the lead stored in the bones, as the result, for example, of certain infections which disturb the mineral equilibrium of the body.

Prophylaxis and Treatment.—Treatment being quite unsatisfactory, every effort should be made to prevent absorption of lead through prolonged contact. In children, this means especially avoidance of toys and other objects painted

in lead colors, because of their well-known habit of putting such things in their mouths. Once plumbism occurs, removal of the lead (*i. e.*, by producing an alkalosis or acidosis, giving parathyroid hormone, reducing the amount of calcium ingested, etc.) is probably inadvisable, because of the danger of mobilizing the lead which may have been deposited in the bones, thus intensifying the symptoms. Since the metal is relatively inert when deposited in the bones, this should be encouraged by means of the administration of lime salts and alkaline phosphates, and perhaps adding vitamin D (viosterol, etc.) to the diet. Eventually, there is then the prospect of its gradual elimination through natural channels.

In addition, convulsions may require the use of sedatives. Unfortunately, treatment is rarely very effective.

EPIDEMIC ENCEPHALITIS

(a) **Lethargic (von Economo) Type.**—Although it seems probable that this disease was first noted many years ago, to von Economo belongs the credit of again calling attention to it, in a classical description of a Viennese epidemic in 1916. Since then it has been reported from practically all parts of the world.

Etiology and Pathology.—The cause is unknown, although it is usually considered to be one of the diseases due to a filtrable virus. Attempts have been made to establish a relationship between this disease and the virus of herpes simplex (fever blisters) and epidemic hiccup, but this claim has never been substantiated. Nor is the manner of its spread clear, although it is assumed that exposure to "carriers" or unrecognized cases of the disease are probable factors in its

transmission. This type of encephalitis is distinctly a winter disease, and despite its name, no extensive or sharply circumscribed epidemics have ever occurred. No age is exempt, but multiple cases in a family are rare. The incubation period is probably between one and two weeks.

The characteristic pathological lesions are those of the central nervous system, the lesions being confined almost entirely to the gray matter, especially the basal ganglia and adjacent structures. Hence, lesions may be found in the cranial nerve nuclei, the globus pallidus, subthalamic nuclei, substantia nigra, medulla and pons. In acute cases the microscope reveals marked capillary engorgement, petechial hemorrhages, small thrombi, and infiltration of cells about the vessels, with a certain amount of degeneration in the nerve cells. In chronic cases, the perivascular infiltration is less pronounced, but there is visible a greater amount of nerve cell degeneration with neuronophagia and proliferation of neuroglial cells.

Symptoms.—The symptoms are so varied and bizarre, and exhibit so much diversification in different epidemics as to make concise description almost impossible. The onset, in most cases, is very gradual, although occasionally the exact opposite may occur, with symptoms so stormy as to be highly suggestive of meningitis. In the latter instances there may be more or less fever, headache, vertigo, ophthalmoplegias (especially ptosis) and even some degree of neck rigidity with positive Kernig and Brudzinski and possibly convulsions. Occasionally there is violent delirium or marked choreiform movements. Within a few days, however, increasing somnolence develops and from this point the course is apt to resemble that of the common type of the disease in which the onset is more gradual. In these, so insidious is the onset as to make the exact date of its occurrence quite uncertain. Often there is a history of malaise, lassitude, and perhaps chilly sensations, occasionally with transient blurred vision or vertigo. Among the commonest early symptoms are ptosis and double vision (from strabismus), with a suggestion of masklike

facies, to be followed within a short time by a gradually increasing drowsiness. In some instances, however, instead of somnolence there is sleeplessness and hyperexcitation, superseded later by the characteristic lethargy. Although slight fever is frequent in the early phases of the disease, it has no distinctive pattern and is often overlooked. Occasionally there may be abrupt elevations to 104° F. or more for a short time, or even a typhoid course. Mild leukocytosis is the rule in the early part of the course, but the blood picture may be quite normal.

The *spinal fluid* in the acute stage of epidemic encephalitis will show, as a rule, a moderate increase in pressure and globulin, with a slight increase in cells, ordinarily less than 100, though higher counts are occasionally encountered. The cells are usually of the mononuclear variety. There is no reduction in sugar or chlorides.

As the disease progresses, the widest variation in symptoms may occur, many of them so bizarre as to make classification practically impossible. Mention has been made of the frequency with which ophthalmoplegias and somnolence occur, but it must be remembered that at times both these symptoms may be absent during the entire course. Ocular manifestations are especially infrequent in the so-called "meningitic type" in which the signs of meningeal irritation may be pronounced in the early phases, but the course is much shorter than the average, and recovery often seems complete. But of especial significance in differentiating the so-called "lethargic" encephalitis from practically all others is the great tendency for *new symptoms to appear months or even years after the onset* of the disease, indicating continued activity of the pathologic process in the brain. So we may have more or less complete coma for many months, or apparent consciousness but indifference to surroundings, changes in the psyche, tearing up bed clothes, grinding objects in the teeth, tremors in one or more extremities or twitching and perhaps rhythmical clonic movements. When the latter involve the respiratory muscles, hiccup and queer barking or clucking sounds, or

merely attacks of rapid and irregular breathing may develop. Speech is apt to be slow and drawling, and there may be spastic paralysis of one or more extremities, or transient facial weakness.

One of the most striking of these late manifestations is that referred to as parkinsonism, in which the masklike immobility of the features with staring eyes and drooling saliva, the rigidity of the muscles with slowing up of volitional movements, and the monotonous, jerky voice all suggest a marked degree of mental impairment. Tremors, too, are common, especially of the head and extremities, and the typical shuffling, hurrying gait of parkinsonism (propulsion or retropulsion) may occur. Examination of the pupils may reveal them to be normal, unequal, contracted or dilated, but more significant is the frequent failure to react to accommodation, and less commonly to light. The fundus is usually normal. Mention should also be made of the so-called "oculogyric" crises, in which there is a transient spasmodic conjugate upward deviation of the eyes. The multiplicity of symptoms is not hard to understand when one remembers the widespread distribution of the pathologic lesions, and that the process seems to be progressive, and for the same reasons it is obvious that there may be a great variety of mental symptoms indicative of changes in the higher cerebral centers, including the occasional occurrence of focal or generalized epileptic manifestations.

Prognosis.—This is always serious, not only because of the relatively high mortality, but also because of the many patients left with tragic sequelae which are often permanent. Although the immediate mortality varies in different epidemics, it is usually stated as between 25 and 40 per cent. It must be remembered, too, that even though the patient appears to have made a complete recovery, the disease may again flare up months or even several years later, and death possibly result. In the chronic cases, death may be the result of some intercurrent infection brought on by the long period of invalidism. Nevertheless, some patients recover completely.

—about 14 per cent, according to von Economo. The meningitic type, with rather stormy onset and short course, offers the best prognosis in this respect. Possibly if more of the milder cases were diagnosed, the outlook would appear considerably more hopeful.

Treatment.—This is largely symptomatic, since no specific remedy is available at present. The use of so-called “convalescent” serum is hardly justifiable because not only is it unlikely that this would influence a virus disease which has already affected the cells in the nervous system, but it is difficult to determine when a prospective donor is definitely recovered and no longer harbors the infectious agent. In the acute stage the intravenous injection of 20 per cent dextrose solution, or perhaps better, a 40 per cent sucrose (cane sugar) solution, in the same dose, occasionally seems beneficial, and supplies fluids and nourishment. Sedatives, such as phenobarbital, may be required for periods of excitement, in conjunction with hydrotherapy. In the late stages, muscular rigidity, myoclonic and ocular spasms have been treated with hyoscine hydrochloride or tincture of stramonium with occasional apparent improvement. The chief reliance, however, for all stages of the disease would seem to rest on hygienic care and keeping up the nutrition, if necessary by forced feeding through a nasal catheter.

(b) **Japanese “Type B.”**—In Japan, a number of summer epidemics of encephalitis have been reported, characterized by a short, stormy course, absence of ocular manifestations, high mortality (from 50 to 90 per cent) and relatively few sequelae in the recovered cases. The disease showed a marked predilection for the older age group, although children were also affected.

Pathology.—The chief lesions were in the gray matter of the brain stem, cerebral hemispheres and upper levels of the cord. They consisted of hyperemia, petechial hemorrhages, perivascular infiltration of cells, with a certain amount of degeneration of nerve cells.

Symptoms.—The onset was frequently abrupt with high

fever and meningeal symptoms, occasionally preceded by a short period of malaise, lassitude, chilly sensations and muscular pains. Neck rigidity, positive Kernig sign and a variety of inconstant reflex changes were common, but ocular symptoms were strikingly infrequent. Fever, up to 104° to 105° F., was usually highest at the onset, and fell rapidly to normal, in most cases, within a week or ten days. Somnolence, mental confusion and tremors were common, but actual paralysis relatively rare. The spinal fluid revealed a moderate increase of mononuclear cells and globulin. In nonfatal cases, the course was short, fever three to fourteen days, and then followed rapid recovery with only occasional residual manifestations.

(c) **Australian X Disease.**—In 1917 and 1918 several small epidemics of encephalitis were reported from Australia, also in the hot season, and very similar in symptomatology to the Japanese Type B disease. Nearly 50 per cent of the cases occurred in children under five years of age, and the mortality was 70 per cent. The pathology and the symptoms were similar to those of the Japanese epidemics, and in addition, frequent mention was made of blinking of the eyes, grinding the teeth, and alternate protrusion and retraction of the tongue. High temperatures were frequent in the early phases of the disease, but ocular manifestations and involvement of the cranial nuclei were rare. The same rapid recovery and absence of residuals was noted in nonfatal cases. Cleland and Campbell reported the successful transmission of the disease to several monkeys and sheep.

(d) **The St. Louis Encephalitis Epidemic of 1933.**—This epidemic, unique in this country because of its occurrence during the summer months, and the number of persons affected within a limited geographical area, was strikingly similar in symptomatology to the Japanese Type B encephalitis. The first cases appeared in the middle of July and the disease rapidly reached epidemic proportions, eventually spreading, but to a lesser degree, to communities several hundred miles away. By the end of the epidemic, in November, it

St. Louis and the territory immediately adjacent, about 1100 cases had been reported, with a mortality of 20 per cent. Although all ages were affected, there was a distinct preference for older individuals, in whom the death rate increased with the age. There were 131 cases reported under fifteen years of age, the mortality, however, being approximately 5 per cent in this group. Multiple cases in the same household and contact between affected individuals were both very uncommon, and the method of spread is still obscure. Transmission through mosquitoes, milk and water seem fairly well ruled out.

Etiology.—One month after the first clinical recognition of the disease, Muckenfuss, Armstrong and McCordock announced its successful transmission to monkeys, the etiologic agent apparently belonging to the filtrable virus group. Almost immediately Webster and Fite reported equal success in infecting mice with a similar technic (intracerebral inoculation). Later it was shown that mice could also be inoculated by intranasal instillation of the virus. Serological studies on recovered patients were reported showing that a large percentage had virus-neutralizing substances in the blood, but that blood from patients who had been affected with the lethargic and other forms of encephalitis had no such properties. Tentatively, then, it may be assumed that the disease was caused by a hitherto undescribed filtrable virus.

The *incubation period* in monkeys was usually eight to fourteen days, and five days in mice. In human beings it is probably between eight and fourteen days also, although this point is still not definitely established.

Pathology.—The characteristic lesions are in the central nervous system and consist of intense congestion with petechial hemorrhages, cellular infiltration and degenerative changes in the nerve cells. In addition to the cuff-like infiltration of round cells about the blood vessels small focal collections of cells occurred elsewhere in the cortex, midbrain, medulla and pons and upper levels of the cord, but except in the most severe cases, there was no especial predilection for the process to involve the basal nuclei.

Symptoms.—The symptoms are in part those commonly observed in many systemic infections and in addition certain manifestations indicating an involvement of the central nervous system. The latter form the picture recognized as encephalitis and bear a marked resemblance to those described in the Japanese epidemics as the "Type B" infection, to differentiate it from the well-known von Economo or lethargic encephalitis. Briefly, these consisted of an abrupt onset with high fever, meningeal symptoms but without ophthalmoplegias, and in nonfatal cases, rapid recovery, as a rule without sequelae. Their more detailed description may conveniently be divided into three groups, although often one type merged insensibly into the other.

Type I.—The most frequent type of the disease in the 1933 epidemic was that in which the cerebral symptoms were predominant even in the early phases. Malaise and chilly sensations were complained of, together with intense headache, fever up to 103° to 105° F., and occasionally convulsions. Neck rigidity was frequent but not invariably present, nor was it an indication of the severity of the infection. At the same time, there was, in all but the mildest cases, a striking change in the mental condition, varying from mental confusion and drowsiness to marked lethargy, delirium or even coma. As a rule, however, patients could be aroused to answer questions, but were disoriented as to time and place and often had no realization of where they were, or what had transpired in the early part of their illness. Rarely, insomnia and hyperexcitation occurred instead of lethargy. Tremors, especially of the hands, tongue and lips, were common, and speech was thick and slurred and often unintelligible. In a few instances complete aphasia developed. Ataxia of a cerebellar nature was also encountered, but was rare, and usually of short duration (ten days to two weeks). The neurological signs varied in different patients and were very changeable even in the same patient. They included stiffness of the neck or spine, positive Kernig, abnormal plantar reflexes, absent abdominal reflexes (especially in adults), and irregular changes in the

knee jerks which were normal or exaggerated at certain times and perhaps absent at others. Ocular manifestations, however, such as ptosis and double vision, which are common in von Economo's type of encephalitis, were conspicuously absent in all but the rarest cases, and were then quite transient. A few patients complained of slightly blurred vision for a day or two at the onset of the disease, and occasionally slight nystagmus was noted. Pupillary reflexes and changes in accommodation were rare. The fundus was usually quite normal.

Among other but infrequent manifestations, one of the most important was paralysis, consisting, in severe cases, of mild or occasionally persistent facial weakness, and in others of spasticity of one or more extremities. Fortunately, recovery from the latter had usually occurred within one or two weeks. Mild exophthalmos was observed in some patients, but in one instance, at least, it was extreme. Changes in the pulse rate also occurred, some patients having a tachycardia, but more frequently a bradycardia was noted. The fever, which was highest in the first few days of the disease, usually fell by rapid lysis or even crisis to the normal within eight to ten days of the onset, with exceptional instances in which it persisted, of an irregular type, for several months. Likewise, mental confusion, which ordinarily had cleared up within a week or two, in severe cases remained for weeks or months after the temperature had returned to normal. As a rule, however, recovery was surprisingly rapid, and within three weeks from onset the patient was apparently entirely recovered.

The *spinal fluid*, during the acute stages, was moderately increased in amount and pressure, with a cell count, predominantly mononuclears, of from 50 to 300, or occasionally as high as 500 to 1000. The globulin was somewhat increased, but not excessively so, even in cases with a high cell count, and the sugar content was normal or slightly above this figure.

Type II.—In this group the encephalitis symptoms were preceded by a definite *period of invasion*, usually of one to

Symptoms.—The symptoms are in part those commonly observed in many systemic infections and in addition certain manifestations indicating an involvement of the central nervous system. The latter form the picture recognized as encephalitis and bear a marked resemblance to those described in the Japanese epidemics as the "Type B" infection, to differentiate it from the well-known von Economo or lethargic encephalitis. They included stiffness of the neck or spine, positive Kernig, abnormal plantar reflexes, absent abdominal reflexes (especially in adults), and irregular changes in the

knee jerks which were normal or exaggerated at certain times and perhaps absent at others. Ocular manifestations, however, such as ptosis and double vision, which are common in von Economo's type of encephalitis, were conspicuously absent in all but the rarest cases, and were then quite transient. A few patients complained of slightly blurred vision for a day or two at the onset of the disease, and occasionally slight nystagmus was noted. Pupillary reflexes and changes in accommodation were rare. The fundus was usually quite normal.

Among other but infrequent manifestations, one of the most important was paralysis, consisting, in severe cases, of mild or occasionally persistent facial weakness, and in others of spasticity of one or more extremities. Fortunately, recovery from the latter had usually occurred within one or two weeks. Mild exophthalmos was observed in some patients, but in one instance, at least, it was extreme. Changes in the pulse rate also occurred, some patients having a tachycardia, but more frequently a bradycardia was noted. The fever, which was highest in the first few days of the disease, usually fell by rapid lysis or even crisis to the normal within eight to ten days of the onset, with exceptional instances in which it persisted, of an irregular type, for several months. Likewise, mental confusion, which ordinarily had cleared up within a week or two, in severe cases remained for weeks or months after the temperature had returned to normal. As a rule, however, recovery was surprisingly rapid, and within three weeks from onset the patient was apparently entirely recovered.

The *spinal fluid*, during the acute stages, was moderately increased in amount and pressure, with a cell count, predominantly mononuclears, of from 50 to 300, or occasionally as high as 500 to 1000. The globulin was somewhat increased, but not excessively so, even in cases with a high cell count, and the sugar content was normal or slightly above this figure.

Type II.—In this group the encephalitis symptoms were preceded by a definite *period of invasion*, usually of one to

four days' duration, but occasionally a week or more. During this time there was moderate fever, with malaise, headache, chilliness or even well-defined chills, nausea, abdominal pains, and almost invariably grippe-like pains in the back and extremities. Photophobia and mild conjunctivitis were noted in some patients, as well as mild sore throat. At this stage the similarity to influenza was marked, as the temperature, as a rule, fell within one or two days and all the symptoms were markedly ameliorated. Suddenly, however, the fever again rose abruptly, the headache became much worse, and drowsiness, mental confusion, tremors and nuchal rigidity developed. Thereafter, the course was similar to the Type I infection, the period of invasion apparently not affecting the prognosis.

Type III.—In this class are placed the mild or abortive cases, in which the diagnosis would probably never have been suspected but for the fact that there was an epidemic of encephalitis in the community. Some degree of fever and headache was usually present, and often a slight tremor of hands and tongue, with absent abdominal reflexes, especially in adults, these being usually normal in children, and perhaps a suggestion of neck rigidity or positive Kernig. Chilliness and muscular pains were common but milder, and the sensorium was usually clear. The spinal fluid, however, showed the same changes as those observed in the other types of infection. Recovery was, of course, more rapid in such cases, and sequelae almost never occurred.

The *blood count*, in all types of the disease, was quite variable, showing a slight leukocytosis in some cases, whereas others had a marked leukopenia. The Schilling hemogram, as a rule, showed a slight shift to the left.

Complications.—Most of the complications occurred in older individuals in connection with such preexisting pathology as cardiorenal disease, arteriosclerosis, hypertension, etc. The most frequent immediate cause of death, however, aside from the toxemia of the infection, was broncho- or lobar pneumonia.

Prognosis.—The mortality for all reported cases was 20 per cent, being higher in the aged and lowest in children (only

5 per cent in those under fifteen years of age). In nonfatal cases recovery was usually rapid and apparently complete, except for occasional subjective symptoms, such as nervousness, fatigue, apprehensiveness for the future, etc. However, in certain instances mental changes, spastic paralysis, tremors and even fever, persisted for a number of months after the initial attack. A check-up of a large number of patients one and two years after their illness failed to reveal the development of new symptoms such as is commonly observed in the old von Economo type of encephalitis. Moreover, the blood of such recovered patients in many instances showed neutralizing substances against the virus believed to be the specific cause of the infection, and hence it seems unlikely that there will be any further progression of the pathologic process.

Differential Diagnosis.—The grippe-like pains and aches, with chilly sensations were often mistaken for influenza or malaria in the cases with a definite period of invasion. Likewise, the leukopenia and bradycardia of others suggested the possibility of typhoid. Development of the neurologic symptoms and spinal fluid changes easily differentiated between these various infections. Tuberculous meningitis and poliomyelitis, however, provided greater problems in diagnosis. The more gradual onset of tuberculous meningitis, the tuberculous focus elsewhere, and the lower spinal fluid sugar, presence of tubercle bacilli and invariably fatal outcome usually served to distinguish between the two diseases. In poliomyelitis, the clear sensorium, absence of speech involvement and flaccid paralysis of certain muscle groups are so characteristic as to establish the diagnosis eventually. Acute disseminated encephalomyelitis associated with infections ("postinfection encephalitis") may be almost indistinguishable from the St. Louis type, particularly in nonfatal cases. In such cases, the history, and possibly tests to determine the presence in the blood stream of neutralizing substances for the specific virus of the St. Louis cases were helpful, but it must be confessed that differentiation between the two diseases was not always possible, except at autopsy.

Treatment.—The therapy employed was largely symptomatic. The use of convalescent serum or other so-called "specific" measures could hardly be expected to be effective, firstly, because when once a virus disease becomes established and produces symptoms, it is generally considered to be beyond the reach of specific therapy, and secondly, because in most cases recovery was so rapid as not to require any treatment beyond the general measures used in any serious infection. Dehydration of the tissues should be prevented by means of the subcutaneous injection of Hartmann's or Ringer's solution and the intravenous administration of 20 per cent dextrose or 40 per cent sucrose (cane sugar) solution. The sucrose solution is used in the same dosage as 20 per cent dextrose; both provide fluid and food, and theoretically, at least, may be of some value in lessening cerebral edema and possibly minimizing nerve cell damage. In unconscious patients and those unable to swallow, feeding may be carried out through a nasal catheter. Lumbar puncture as a rule relieves the headache, and may quiet nervous irritability, although marked delirium with hyperexcitation will perhaps require sedatives, such as phenobarbital or bromides.

ACUTE DISSEMINATED ENCEPHALOMYELITIS ASSOCIATED WITH INFECTIONS

(Postinfection Encephalitis, Para-infection Encephalitis, Postvaccinal Encephalitis)

It has long been known that serious disturbances of the nervous system occasionally accompany or follow one of the infectious diseases. This is especially true of those diseases caused by filtrable viruses, although clinically similar manifestations may at times follow other bacterial diseases apparently not associated with viruses. From the number of reports in the literature, it would seem that the incidence of encephalitis or encephalomyelitis of this nature has shown a considerable increase within the last few years. Since the precise factors which bring about such disturbances in the nervous system are unknown, and autopsies have been too few

to permit of their final classification on the basis of the pathological processes involved, it is convenient, for purposes of discussion, to place them tentatively in the same group.

Etiology.—Although postinfection encephalitis seems commonest in association with the virus diseases, there are apparently exceptions to the rule. For example, the list includes measles, mumps, pertussis, vaccination against smallpox (vaccinia) and less frequently, rubella, varicella, variola, antirabic inoculations, scarlet fever, typhoid and paratyphoid fever, lobar pneumonia and bacillary dysentery. In addition to these, a number of cases of encephalitis have been reported associated with influenza or upper respiratory symptoms, although it is not clear whether such participation of the respiratory tract represents the early manifestations of the encephalitic period of invasion, or constitutes the predisposing cause.

Because of the similarity of the encephalitic symptoms in otherwise widely different diseases, it has been suggested that the encephalomyelitis is a separate and distinct disease, due to some hypothetical, specific neurotropic virus which in some way becomes activated by the antecedent infection. However, this question cannot be definitely answered in the present state of our knowledge.

Pathology.—Although the small number of careful autopsy studies does not permit of definite conclusions in the case of each one of the diseases mentioned, the pathologic picture has been well established as quite similar in the encephalitis of measles, smallpox vaccination and antirabic inoculations. The same is apparently true of variola, varicella, rubella, and possibly some of the other diseases, although the reports are too few to establish this with certainty. The characteristic lesions of the central nervous system are areas of perivascular demyelination and a cuff-like ring of mononuclear cells about the blood vessels. Petechial hemorrhages and congestion are common, but as a rule, there is relatively little injury to nerve cells or axis-cylinders. The process affects both gray and white matter, the lesions in the latter

being usually more extensive. Not infrequently they involve the cord as well as brain.

The pathology of pertussis encephalitis reveals less tendency to destruction of nerve cells, with areas of cerebral atrophy as a late result. It is quite possible, too, that in mumps encephalitis and "mumps meningitis" the lesions differ from those in measles, for example, but autopsies are so infrequent in mumps as to leave this point unsettled. Indeed, it is not known whether mumps meningitis and encephalitis are really the same disease, possibly a meningo-encephalitis, differing only in the degree and location of the lesions, or two entirely different processes.

Symptomatology.—*Measles.*—Encephalitis is commoner after measles than any other of the exanthemata. The onset is usually two to five days after the first appearance of the rash, rarely in the prodromal period, and the occurrence of neurologic symptoms apparently bears no relation to the severity of the infection up to this time. Its appearance is sudden, with headache, vomiting, possibly a brief exacerbation of the fever, and almost at once there appear drowsiness, often convulsions, and not infrequently a slightly stiff neck and positive Kernig. Paralysis, either flaccid or spastic, of one or more extremities may occur, and twitching of the muscles, coarse tremors, irritability and aphasia. At times there is delirium or mental confusion. Convulsions are especially common in children, and apt to be repeated during the early part of the illness. Changes in the tendon reflexes and abnormalities of the plantar reflexes may be present, but except in the severer cases, this does not persist for more than a few days.

Other manifestations which may be observed include difficulty in swallowing, facial weakness or paralysis, usually transient, and ataxia of a cerebellar type. Ptosis and double vision are rarely observed. When the process involves the spinal cord, there are usually disturbances of sensation and in the function of the bladder and rectum, and at times a flaccid paralysis of the lower extremities which is often as complete as in any other form of transverse myelitis. Indeed, in general

cord lesions are slow in clearing up and unfortunately may result in permanent disability.

Prognosis.—The subsequent course of the encephalomyelitis is variable, but in probably the majority of cases, recovery is rapid and complete. It is almost incredible that a child with convulsions, aphasia or coma and perhaps complete paralysis of all extremities may seem fully recovered within three or four days after the onset of this illness. In other cases, however, spastic paralysis, tremors and mental deterioration may persist for months, or even be permanent. Cord lesions are somewhat more apt to be followed by such residuals than are the cerebral ones. The mortality rate is probably around 10 per cent, death resulting within a week or ten days as a direct result of cerebral damage, or it may occur much later from emaciation, exhaustion, or some intercurrent infection.

Treatment.—Lumbar puncture may relieve headache and irritability, and intravenous injections of 40 per cent sucrose (cane sugar) or 20 per cent dextrose solutions tend to relieve the cerebral edema and possibly lessen nerve cell damage. The latter measures also supply nutrition and fluids to the body. Subcutaneous administration of Hartmann's or Ringer's solution is of value at times. Otherwise the treatment is symptomatic, the use of convalescent measles serum being both illogical and ineffective.

Rubella.—The encephalitic symptoms appear as a rule one or two days after the first appearance of the rash. Although less common than in measles, the symptoms are in every way comparable. The pathology is assumed to be similar also, although there is insufficient evidence on which to base a positive statement in this respect.

Variola and Varicella.—The encephalomyelitis which occasionally occurs is apparently similar to that of measles, the symptoms usually appearing two or three days after the rash comes out, but occasionally they may be as late as the seventh to tenth day.

Vaccination Against Smallpox.—During the past decade

an ever-increasing number of cases of postvaccinal encephalitis and myelitis have been reported from practically all over the world, being apparently most numerous in Holland. At that, however, the incidence is only 1 in several thousand cases. It is less common in infancy, and although it may occur even after secondary or revaccination, it is considerably more frequent after primary inoculations. There is considerable evidence to show that the causative agent is not contained in the vaccine virus itself, since even when the same vaccine is used, the incidence of encephalitis is much greater in regions where post-measles encephalitis is known to be prevalent than in countries where it has been less common. The pathology, however, is quite similar to that in measles, affecting the gray and white matter of brain and cord, and the characteristic lesion being a process of perivascular demyelination.

The *symptoms* are similar to those occurring in measles, appearing usually ten to twelve days after vaccination, but occasionally earlier or as late as three or four weeks after vaccination. Fever of brief duration, headache, vomiting and drowsiness or coma appear, often accompanied by slight neck rigidity, positive Kernig and changes in the plantar and tendon reflexes. Convulsions are common, and may be followed by spastic paralysis of one or more extremities. Flaccid paralysis of the legs, associated with incontinence of urine and feces, indicates spinal cord involvement. Speech may be affected, up to the point of complete aphasia, and tremors of hands and lips may be noted. A less frequent occurrence, fortunately not apt to be permanent, is mental deterioration to the point of apparent idiocy. The spinal fluid shows a moderate increase in globulin and mononuclear cells.

Prognosis.—The mortality is usually stated as about 50 per cent, although in our own series of cases it was about the same as in measles, around 10 per cent. In nonfatal cases, recovery is often complete and surprisingly rapid, so that the child may appear to be normal within less than a week of onset. Residual manifestations occur at times, and especially in those with spinal cord lesions.

Prophylaxis.—Whenever possible, vaccination against smallpox should be carried out in infancy, since the incidence of encephalitis at this age is decidedly lower than in later life. However, it may be wise to defer vaccination at such times as infections of the central nervous system (*c. g.*, poliomyelitis, epidemic encephalitis) are prevalent in the community. Moreover, Armstrong has suggested that children be immunized against diphtheria before being vaccinated against smallpox, since diphtheria toxoid apparently renders mice more resistant to intracerebral inoculations with vaccine virus. Again, Rivers has advised using intradermal inoculations of culture virus instead of the usual calf lymph, since he feels the purity of the product and the mildness of the reactions produced may avoid the sequel of encephalitis.

Treatment.—This is similar to that described under measles encephalitis. It has been suggested that the serum (usually 10 cc. or more) from another individual who gives a history of a recent successful vaccination be used intravenously or intramuscularly, but it seems unlikely that this would ever prove effective, once the disease is established and symptoms have appeared.

Antirabic Inoculations.—During the Pasteur treatment for the prevention of rabies in rare instances the development of encephalitis has been reported. Pathologically and clinically this appears to be similar to that associated with vaccination against smallpox and in measles. The same process of demyelination occurs, and the course and prognosis are similar to those described above. The symptoms may appear at any time during the course of the treatment, but especially during the last of the series of injections.

Mumps.—Symptoms referable to the central nervous system occasionally occur in mumps, and in the absence of data concerning the pathological process, are usually divided into two clinical groups, mumps encephalitis and meningitis. It is possible that the two are really variations of the same disease, a meningo-encephalitis. In mumps meningitis, the onset is usually at the height of the disease, or may even precede the

involvement of the salivary glands; there is high fever, and invariably stiff neck and positive Kernig and Brudzinski signs. The spinal fluid shows a high cell count (5000–6000 or more), the mononuclear cells predominating. In the encephalitic form, on the other hand, the meningeal signs are less prominent and the cell count lower, as in measles and postvaccinal encephalitis. Despite the serious symptoms, recovery, even in meningitis, is the rule, although in rare instances the patient may be left with a permanent spastic paralysis of one or more limbs, blindness, deafness, or even idiocy.

Pertussis.—The neurological complications of whooping cough are well known and relatively common. This is especially true of convulsions without other evidence of cerebral injury. But occasionally there is a sudden onset of paralytic symptoms, often a hemiplegia, with somnolence or even coma. Inasmuch as nosebleed and subconjunctival hemorrhages are quite frequent in pertussis as the result of the severe paroxysmal cough and its changes in the circulation, the paralysis may be attributed to intracranial hemorrhage and perhaps operation advised. However, encephalitis should always be ruled out first, and a search made for stiff neck, and positive Kernig, which, in the absence of fundus or blood pressure changes, would speak more for encephalitis than hemorrhage. In encephalitis the spinal fluid shows the characteristic increase of mononuclear cells, but lumbar or cistern puncture should be performed most cautiously after careful examination of the patient, for in hemorrhage the brain may be jammed down into the foramen magnum and sudden death result from spinal drainage. In encephalitis the coma and paralysis often clear up within a few days, but occasionally residuals, such as spastic paralysis, tremors, visual disturbances or mental changes may persist for weeks, or even be permanent.

It seems likely that the pathological changes in pertussis encephalitis are somewhat different than the others described above, although the question cannot be settled until more autopsy studies are available. Reports have mentioned a more

extensive atrophy of the cortex and neuron degeneration, without reference to myelin destruction. Including this type of encephalitis in the postinfection group, however, seems justifiable on the basis of clinical symptoms until further knowledge of the condition is gained.

"Influenza" and Other Respiratory Infections.—In many cases of encephalitis which, except for the antecedent infection, are indistinguishable from the postinfection type described, there is a history of a preceding group of mild upper respiratory or influenza-like symptoms. These include mild sore throat, rhinitis, chilly sensations, headache, lassitude, prostration, and pains in back, limbs or abdomen. It is impossible to say at present whether these constitute the predisposing cause, or represent the invasive symptoms of the encephalitis itself. But, in some instances, the encephalitis has followed a definite lobar or bronchopneumonia. The neurologic manifestations are similar in onset and course to those seen in measles, after vaccination, etc. The prognosis is apparently about the same, many cases showing a surprisingly rapid recovery, and residuals being only occasionally met with.

Encephalitis Associated with Other Infections.—Encephalitic symptoms similar in every way to those after measles are occasionally seen in association with other infections. In our experience, this occurs oftenest after typhoid fever, during the period of convalescence, but it has also been observed after paratyphoid, scarlet fever, bacillary dysentery and even pyelitis. They may be placed in the postinfection group of encephalitides until further knowledge permits of a more accurate classification.

UNCLASSIFIED TYPES OF ENCEPHALITIS

Numerous reports have appeared in the literature describing an encephalitic syndrome under various names, among which may be mentioned "serous meningitis," "acute benign idiopathic serous meningitis," "acute aseptic meningitis," "acute lymphatic meningitis," "meningismus," etc. In most instances the symptoms consist of signs of meningeal irrita-

tion, with an increase of pressure, globulin, and mononuclear cells in the spinal fluid. With the exception of a group of cases in young children described by Brown and Symmers, most of these cases cleared up rapidly, the patients showing no residual manifestations.

Under the name of "acute serous meningitis" Brown and Symmers described a group of 10 cases, all terminating fatally, in which the symptoms began abruptly with irritability, vomiting and diarrhea, frequently a sore throat, and high fever. Among other symptoms they mention convulsions, coma, irregular respiration, ptosis and strabismus, nystagmus, papilledema, muscular twitchings, retraction of the angles of the mouth, neck rigidity with positive Kernig and occasionally paralysis. Pathological studies showed a marked hyperemia and edema, and at times vacuolization of the ground substance and cloudy swelling of the pyramidal cells. There seems no way at present of arriving at a more accurate classification of this type of case. Indeed, it is highly important that experiences with various types of encephalitis, and especially those fatal cases in which careful autopsies have been performed, be placed on record to further a better understanding of the subject.

CLINIC OF DR. H. L. ALEXANDER

FROM THE DEPARTMENT OF MEDICINE, WASHINGTON UNIVERSITY SCHOOL OF MEDICINE AND BARNES HOSPITAL

THE EARLY DIAGNOSIS AND TREATMENT OF EMPHYSEMA

UNTIL a few years ago, a good deal of confusion existed concerning the significance of emphysema. Given two barrel-chested individuals with evident emphysema of approximately the same degree, one may be completely disabled because of dyspnea on slight exertion and the other capable of hard physical labor. The separation of patients into two groups, those with symptoms of respiratory dysfunction, notably dyspnea and cyanosis, and those without such symptoms, has led to clarification.¹ The latter patients, in whom their apparent emphysema seems no handicap, were found to have a stiffness of the spine. Investigation of this lesion revealed that all such cases were due to a swelling of the intervertebral disks which resulted in a straightening of the spine. Since the ribs are attached posteriorly to the vertebrae, then, as the back straightens the ribs elevate. The same effect is observed when an individual stands up very straight. His ribs are thrown upward, and a typical barreling of the chest results (Figs. 27, 28). The lungs follow the chest wall as the process develops, but there is nothing inherently wrong with them. Patients with so-called "senile emphysema," so commonly seen, have stiffened spines in which degenerative processes in the disks are present. As the lesion progresses the bony substance of the vertebrae becomes involved, and finally the spine may collapse (Fig. 29), and dorsal kyphosis occurs. The barrel

Fig. 27.—Thoracic cage of a normal cadaver from which all muscle has been removed. The upper edge of the sternum stands at 15 inches on the scale. (From Kountz and Alexander in "Medicine," September, 1934, Williams and Wilkins Co., Publishers.)

Fig. 28.—The same model as Fig. 27. The thoracic spine has been straightened. The upper edge of the sternum stands at 17 inches. The distance of the chest from the spine to the sternum has been increased $1\frac{1}{2}$ inches. (From Kountz and Alexander in "Medicine," September, 1934, Williams and Wilkins Co., Publishers.)

chest then becomes exaggerated, but the lungs, other than stretching moderately to keep in contact with the changing chest wall, do not suffer structural damage. Vital capacity and oxygen saturation values in the arterial blood usually remain within normal limits unless there is a coincident cardiac failure.

The first step in the diagnosis of emphysema is to distinguish whether the barreling of the chest and hyperresonant lungs are due to a lesion of the lungs or of the chest wall. If

Fig 29.—Spine cut longitudinally from a case of postural emphysema. The swollen intervertebral disks with invasion of vertebral bodies and collapse of the spine are seen.

the latter, it is of little consequence, since this is not really emphysema in a pathological sense, as the lungs are neither structurally nor functionally involved. Such cases are easily distinguished from those with true emphysema. Measurements of vital capacity are within normal limits, there is no cyanosis, no dyspnea, and the diaphragm has free movement. Moreover, the dorsal spine is limited in its movement, and the thoracic curve is either flattened out or in the late cases with collapse, greatly exaggerated. These patients with so-called

"postural emphysema" represent the majority of cases and require only diagnostic consideration.

* Based on Dreyer's Tables.

(From Kountz and Alexander in "Medicine," September, 1934, Williams and Wilkins Co., Publishers.)

True emphysema in which the alveoli are stretched and torn is a serious disease because the structural damage to the lungs is irreparable. It results from bronchial obstruction with few exceptions, such as extreme compensatory emphysema after a large portion of the lungs has been destroyed. emphysema induced by work at very high altitudes, and the great stretching and tearing of pulmonary tissue occurring occasionally during prolonged confinement in certain respirators. The forces of inspiration, which pull air past partially occluded bronchi, are greater than those of expiration which depend largely on the elasticity of the lung, and the squeeze of thoracic and abdominal muscles. In the course of time air accumulates distal to the bronchial obstruction, and the alveoli distend to the point of loss of elasticity and final rupture.

The commonest causes of bronchial obstruction are the lesions of asthma and bronchitis. The sticky exudate from overacting mucous glands tends to plug the finer airways, and the smooth muscle in the walls of the bronchi, greatly hypertrophied after years of bronchospasm and cough, remains in a state of hypertonus, so that there is more or less constant spasm. Distal to this narrowing, which occurs chiefly in the bronchioles, more and more air becomes trapped.

The acute ballooning out of the lungs during a paroxysm of bronchial asthma, wherein the position of deep inspiration is assumed, portrays in part what occurs when the lungs are chronically distended. The diaphragm is flattened out in its position of contraction, because the lungs crowd downward toward the abdominal space as they gradually enlarge. As they continue to distend the intrapleural pressure increases, and the thorax in time takes the position of deep inspiration. With the diaphragm held in the position of contraction and the chest distended, the ability to take a deep breath is greatly impaired. Measurement of vital capacity, which records the amount of air exhaled from deepest inspiration to greatest expiration, is reduced at times 75 per cent below normal values. The patient then is unable to do any exertion without shortness of breath.

Unfortunately, neither the frequency nor significance of obstructive emphysema is generally recognized. Many such patients are thought to be suffering from heart trouble, since the symptoms and signs of cardiac decompensation and true emphysema are the same. These include dyspnea, cyanosis, râles in the chest, low vital capacity and high venous pressure. Treatment of the heart brings no improvement excepting in cases in which the heart eventually becomes affected.

The diagnosis of true emphysema in its early stages becomes important, since not much can be accomplished after the lungs have been largely destroyed. Moreover, dyspnea does not occur until the disease has progressed far, so that early recognition is of great advantage. The first step is to be conscious of the fact that the great majority of patients

with chronic bronchitis and prolonged asthma sooner or later develop emphysema. The next is to place such patients under the fluoroscope and observe diaphragmatic excursions. As stated above, the early direction of pulmonary distention is downward. Normally, as the diaphragm contracts it moves toward the abdomen from its domed position of relaxation, and its vertical excursion may measure some inches on deep

Fig. 30.—Orthodiagrams of maximum diaphragmatic excursion, *a*, in a patient with postural emphysema; *b*, in a patient with asthma and obstructive emphysema. The patient was of the same general body type in each case (From Kountz and Alexander in "Medicine," September, 1934, Williams and Wilkins Co., Publishers.)

inspiration. When encroached upon by the distending lungs and pushed down toward its position of contraction, its movement becomes less and less and finally ceases. Breathing is done then entirely with the thorax (Fig. 30).

If a patient with bronchitis or asthma shows limitation of movement of the diaphragm, his vital capacity should be taken on any ordinary spirometer. Normally this should be 3500 to

4000 cc. or more for adults. If the vital capacity remains at such values, the emphysema has not progressed to the point of interference with respiratory function. Lower readings even without symptoms of dyspnea indicate probable structural alveolar changes (Table 2).

*Based on Dreyer's Tables.

(From Kountz and Alexander in "Medicine," September, 1934, Williams and Wilkins Co., Publishers.)

Physical signs may reveal early emphysema long before barreling of the chest has occurred. Hyperresonance of the lungs, high-pitched vesicular breathing, impairment of movement at the bases and partial obliteration of the area of cardiac dulness are typical. Roentgenograms show hyperventilated lung fields, wide separation between the anterior ribs, a low diaphragm and a spindle-shaped heart which becomes elongated as its base is pulled downward by the diaphragmatic descent.

The search for emphysema in all patients with chronic asthma and bronchitis by observations of diaphragmatic movement, of vital capacity, physical signs and roentgenograms leads to the early recognition of the disease.

Inasmuch as most cases of emphysema result from asthma and bronchitis, prophylaxis consists in adequate treatment of

these two disorders, details of which are beyond the scope of this presentation.

The therapy of emphysema is entirely symptomatic. In the advanced stages there is usually deterioration of health. Anorexia, undernourishment, broken sleep, and loss of muscle tone from inactivity require special attention.

Especial consideration should be given to the bronchial lesions with the purpose of lessening obstruction. A warm climate is desirable because cold air induces cough. If travel is not feasible, warm moist air at home may be secured by simple humidifiers or even with a steam kettle. The dry, dusty air of overheated rooms is distinctly irritating to the bronchial mucosa.

One of the principal causes of cough is the outpouring of tenacious secretion from the mucous glands in the bronchial walls. By lessening the viscosity of the sputum, cough discharges it more easily. Potassium iodide and ammonium chloride are good drugs for this purpose, and are given in 0.3 Gm. doses every two hours, preferably with a cup of water.

The bronchial muscle has been found to be hypertrophied in all cases of emphysema with the exception of a few very advanced ones. Excessive secretion and bronchospasm are the essential lesions which narrow the air ways, and epinephrine has been found to give immediate relief in most cases with marked dyspnea on slight exertion. The drug acts by stimulating the sympathetics and thereby lessens the parasympathetic stimulation of the bronchial muscle and glands. Measurements of vital capacity taken before and after administration of 0.5 cc. of adrenalin chloride² showed an increase as high as 40 per cent whereas in normals the increase is about 10 per cent. Ephedrine in doses of 0.02 Gm. given three or four times a day over a long period has been found more useful than any other single pharmacologic measure.

In cases where there is marked overdistention of the lungs it has been found possible to raise the flattened diaphragm to its position of relaxation from which it can again contract. By so doing the normal process of breathing is resumed. As a

result, the vital capacity is increased, and dyspnea is lessened. This is accomplished by the use of an abdominal belt so devised that pressure is exerted over the lower abdomen just above the symphysis pubis.³ The belt is made of canvas or leather and fits around the abdomen well below the umbilicus (Fig. 31). A pad of sponge rubber attached to the inner

Fig. 31.—Abdominal belt in place. The pad of sponge rubber attached to the inner side of the belt exerts pressure upward and inward in the direction of the screw bolt seen protruding from the lower binder of the belt. A new locking device has supplanted the bolt.

surface of the belt anteriorly is directed inward and upward toward the promontory of the sacrum by means of a steel spring and locking device which can be adjusted from without to suit the comfort of the patient. By such an arrangement pressure is directed upward to the under surface of the diaphragm which is lifted toward the thorax. From its new position of relaxation it contracts, but since the elasticity of

the lungs is lost, they are thrust back by pressure from below during each expiratory phase. Once the belt is adjusted, it is a very effective measure in making breathing easier.

To conclude, the diagnosis of emphysema rests first with the separation of cases due to bronchial obstruction from those of the postural type. The early recognition of the disease depends on fluoroscopic observations of diaphragmatic movement, and measurement of vital capacity in all cases with chronic asthma or bronchitis which emphysema constantly follows. Physical signs reveal the underlying pulmonary distention.

Treatment is directed toward lessening bronchial obstruction and facilitating breathing by mechanically restoring the diaphragm to its normal position.

CLINIC OF DRS. WILLIAM H. OLMSTED, RAY D.
WILLIAMS AND THEODORE BAUERLEIN

FROM THE DEPARTMENT OF MEDICINE, WASHINGTON UNIVERSITY SCHOOL OF MEDICINE AND WASHINGTON UNIVERSITY CLINICS

CONSTIPATION: THE LAXATIVE VALUE OF BULKY
FOODS

CONSTIPATION is a symptom rather than a disease. For a full discussion of its etiology one should consult Hurst.¹ Regardless of its numerous causes we agree with Hurst when he says, "Nearly all patients with constipation are benefited by a suitable diet, even if other treatment has to be simultaneously used." The purpose of this paper will be to discuss the physiological actions of indigestible food residue and to give some practical suggestions in the use of foods for relief of this symptom.

The initial interest of one of us (W. H. O.) began over a dozen years ago with an effort to determine how much absorbable carbohydrate was destroyed by intestinal bacteria. As a measure of the destruction of carbohydrate we took the amount of acetic acid appearing in the stool. In passing, let us say here that the weight of evidence indicates that the stool fatty acids are the best criterion of the extent of carbohydrate fermentation. This work² showed that the stool volumes of our experimental subjects were much higher on diets predominantly composed of sugars or starches than on diets in which protein or fat predominated and that simultaneously with the augmented stool volume of high carbohydrate feeding, the stool volatile fatty acids increased. Lactic acid, which in pure cultures is as frequently produced, and in as large

amounts, as the volatile fatty acids, cannot be demonstrated in the stools. Pittman and Olmsted³ found that lactic acid added to fresh stool material was destroyed. We felt sure that the volatile acids produced on high carbohydrate diets were stimulating to the colon and that the increase in stool bulk was due to increased peristalsis. Since the indigestible carbohydrates are much more effective in increasing stool bulk, we wondered whether in their case also the effects on the intestine might be from the fermentation of cellulose rather than because of their mechanical distention of the intestine, the explanation which has usually been offered.

Indigestible residues consist of cellulose, lignin and hemicellulose. If one examines the analytical data of any cereal, the words cellulose, lignin and hemicellulose do not appear, but one finds the term crude fiber, referring to a method which was devised seventy years ago at Weende, Germany, and today widely accepted by agricultural chemists. According to the method any cereal or vegetable material is digested with both boiling dilute acid and alkali for a given time and the acid and alkali soluble products filtered off. What remains after this double digestion is called crude fiber. Williams and Olmsted,⁴ in a recent paper, showed that crude fiber represents only a variable fraction of the combined cellulose, lignin and hemicellulose. The crude fiber method is of no assistance in determining the individual fate of cellulose, lignin or hemicellulose in the intestinal tract. For this reason Williams and Olmsted defined indigestible residues and proposed a biochemical method for isolating them from the stools and determining separately the amounts of cellulose, lignin and hemicellulose. The method uses simple biological technics for separating true residue from interfering substances in feces or stools and well-recognized chemical methods for subsequent analysis of the residue. The method offers several advantages among which are: (1) It separates indigestible residue into its proper fractions and quantitatively determines each fraction whether in feces or foods. (2) It has been applied to a wide variety of materials and has enabled us to account

for essentially 100 per cent of such materials. Such an analysis by older procedures has been impossible and in such a material as wheat bran 15 to 50 per cent was unaccounted for. With this method not only can the cellulose, lignin and hemicellulose be quantitatively determined in any foodstuff, but after ingestion they can be accurately estimated in the stools.

TABULATION

	Cellulose	Hemi-cellulose	Lignin
Wheat bran	Low	High	Moderately high
Alfalfa leaf	High	Low	High
Corn germ meal	Low	High	Low
Carrots	High	High	Low
Cotton seed hull	Low	High	High
Sugar beet pulp	High	High	Low
Peas	High	Low	Low
Cabbage	High	High	Low
Agar	None	High	None
Cellu flour	High	Low	None

Equipped with this improved technic we concentrated by simple bland procedures the indigestible portions of ten foodstuffs, analyzed the materials and added them to the foods of experimental subjects on a residue-free diet.⁵ The resultant stools were weighed and analyzed by the same method. The comparative analyses of material fed with the material recovered in the stool indicated precisely how much cellulose, lignin and hemicellulose disappeared. A comparison of the weight of the stool on the nonresidue diet with the stool weight when the indigestible materials were added, showed to what extent each material affected bulk. The ten materials selected represented three types of indigestible residue: first, materials whose source was cereals; second, materials whose source was vegetables; and third, materials which had been processed in a manner chemically similar to that used in the production of crude fiber. Representatives from the first type were wheat bran, corn germ meal (this is the remainder of the corn germ after the corn oil has been pressed out) and cotton seed hull (the ground-up hulls of the cotton

amounts, as the volatile fatty acids, cannot be demonstrated in the stools. Pittman and Olmsted³ found that lactic acid added to fresh stool material was destroyed. The comparative analyses of material fed with the material recovered in the stool indicated precisely how much cellulose, lignin and hemicellulose disappeared. A comparison of the weight of the stool on the nonresidue diet with the stool weight when the indigestible materials were added, showed to what extent each material affected bulk. The ten materials selected represented three types of indigestible residue: first, materials whose source was cereals; second, materials whose source was vegetables; and third, materials which had been processed in a manner chemically similar to that used in the production of crude fiber. Representatives from the first type were wheat bran, corn germ meal (this is the remainder of the corn germ after the corn oil has been pressed out) and cotton seed hull (the ground-up hulls of the cotton

seed). Representatives of the second type were carrots, alfalfa leaf, peas, cabbage and beet pulp (the latter is the pulp of the sugar beet after the juice has been extracted). All these materials were coarsely ground, washed overnight with water at 60° C., air dried, and ground to pass a 20-mesh sieve (but not through a 40-mesh) and finally extracted with alcohol. A pound or two of concentrated material from the vegetables represented large amounts of raw materials because the indigestible residue of carrots, cabbage, and peas amounts to from 2 to 3 per cent of the green weight.

The analyses of these products differed in the content of cellulose, lignin and hemicellulose. Most of the materials were concentrated so that the combined cellulose, lignin and hemicellulose represented from 50 to 80 per cent of the total dry weight. The cellulose ranged from 16 to 35 per cent. The lignin in most of these materials was very small. There was enough lignin in bran (8 per cent), alfalfa leaf (15 per cent), and cotton seed hull (21 per cent) to judge the effects. Hemicelluloses ranged from 10 to 35 per cent. Agar was entirely hemicellulose, *i. e.*, 81 per cent. The individual characteristics of these materials is simply summarized in the tabulation. When such materials were fed to subjects on a constant basal, nonresidue diet, the results plainly showed that those materials which contain the most hemicellulose were most efficacious in increasing the weight of the stools. Those materials which contained cellulose were not particularly helpful unless they also contained hemicellulose. Thus cellulose, which is almost entirely cellulose, scarcely increased the weight of the stools above the basal; and peas, which were very high in cellulose but low in hemicellulose, were quite ineffectual. Lignin is not only inactive but whenever present apparently counteracts the effects of hemicellulose. Thus cotton seed hull, which contains a large amount of hemicellulose but also 20 per cent of lignin, did not increase the stool weights to any considerable degree. Alfalfa leaf, a product high in lignin, high in cellulose but low in hemicellulose, only moderately increased the stools.

When the stools were analyzed for the amount of these materials that disappeared, it was of interest to find that the loss of hemicelluloses was greatest. In most instances well over 60 per cent and in three of the materials over 80 per cent disappeared. Only where the lignin was high were bacteria unable to attack the hemicellulose. Cellulose disappeared to a less extent, but bacteria were able to attack it and usually between 50 and 60 per cent was lost. Assuming the volatile fatty acids as the best index of the fermentation of the cellulose and hemicellulose we found their excretion to be greatest when the greatest amount of cellulose and hemicellulose disappeared.

We consider the impressions of our human subjects to be one of the most valuable criteria of the laxative value of the materials. From the standpoint of the subject's sensations of a satisfactory bowel movement, it is the moist, plastic, voluminous stool that is most satisfactory. Interestingly enough it was those materials high in hemicellulose, such as agar, sugar beet pulp, cabbage, and carrots, which gave the most satisfactory stools. In this respect bran, because of its wide use, is important to consider. The stools from it are very bulky but tend to be dry and often irritating. The conclusions in this research were definite, namely (1) that lignin is to be avoided, (2) that cellulose is useful but not nearly so effective as the hemicelluloses. We believe that we are the first to emphasize the differences in the action of cellulose, lignin and hemicellulose on the bulk of the human stool.

INFLUENCE OF INDIGESTIBLE RESIDUE ON DEFECATION

The addition of indigestible residue to the food results in stools of greater weight than can be accounted for by water and the residue escaping degradation. It has been known since the work of Strausburger that half of the stool is composed of bacteria and the greatest part of these are dead. In addition to the bacteria there is in the stools of the fasting animal and in the stools passed on a nonresidue diet, some fat, nitrogen, and minerals arising from the succus entericus and

from the remainder of unabsorbed bile and pancreatic juices. When the diet contains considerable amounts of indigestible residue, the water content is increased, and the total daily output of all of the solids appearing in the fasting stool are increased. More nitrogen, fat and starch are lost. Much of the loss in nitrogen and starch in a diet high in vegetables or whole grain cereals is due to the fact that the intestinal digestive juices are unable to penetrate through the cell membranes and thus some of the digestible protein and starch escapes absorption. It may be that even the mixing of indigestible residue with digestible food material will result in less efficient absorption because of the hastened passage through the intestinal tract. Thus when indigestible residue is added, the increase in bulk of the feces is due not only to water and the indigestible material but to an increase in fats, starch, protein and minerals and all other normal solids which usually appear in the stool. However, the loss in calories resulting from bulky stools is not great, probably (as shown by Rubner) not over 10 per cent more than is lost when the diet is free of indigestible residue.

Hurst, and recently Garry,⁶ discuss fully the physiological movements of the colon. When the normal bowel empties itself, there is a mass peristalsis which entirely empties the whole descending colon from the splenic flexure downward. Feces are constantly present in the cecum, ascending and transverse colon. This fact explains the reason why so often materials do not appear in the feces for many days after their ingestion. Following a normal defecation feces collect in the descending colon down to the rectosigmoidal junction. Normally there are no feces in the rectum. The call to stool is due to the passage of feces from the sigmoid colon into the rectum. Anyone who does routine digital rectal examinations must be impressed with the frequency of inspissated feces particularly in the rectums of women. The call to stool sensation is lost in such individuals, but when the feces descending into the rectum are bulky, the call to defecate is more insistent.

The absorption of water that has taken place in the cecum and transverse colon leaves the feces in a semisolid state in the descending colon. If absorption of water in this part of the colon results in the loss of the plasticity of the mass, the evacuation by mass peristalsis is difficult. Hemicellulose, because of its great attraction for water, prevents overabsorption and at the same time makes a voluminous semisolid mass. The celluloses, at least those that we have examined, are not so hygroscopic and hence the mass of feces they form is apt to be more solid and friction producing.

In what way do volatile fatty acids, and perhaps other products of the chemical degradation of cellulose and hemicellulose, act? On this point we have no experimental evidence. However, it has been shown by the German observers, Bardth *et al.*,⁷ that these acids fed to dogs hasten the evacuation of the bowels. Presumably their presence in the lumen or the wall of the colon stimulates peristalsis or tonicity. Although indigestible residue stimulates the upper intestinal tract as well as the colon, as shown by the shorter period of time that cellulose-containing foods require to pass through the upper intestinal tract, nevertheless it reaches the colon or rather the terminal ileum, where the bacterial flora is prolific, before it is broken down. Thus the stimulating split products of cellulose and hemicellulose are liberated only in the terminal ileum, cecum and the ascending and transverse colon and these are just the areas where stimulation is most needed.

We believe that there are certain acids in some of the fruits that act in much the same way as the split products of intestinal residue. We refer to the acids of raw apple, the juice of the prune and fig and other fruits.

IS IT NECESSARY TO ADD INDIGESTIBLE RESIDUE TO THE NORMAL DIET?

There are few constipated individuals among the well-nourished and obese. It is the asthenic, undernourished woman who is most apt to be constipated. This is explainable by the increased amount of material that the well-nourished

individual eats. His total food mass is much larger. There is no doubt in our minds that rarely would an individual be constipated who is given a liberal diet of vegetables and fruits. To our classes in dietetics we teach that the normal person should consume from $\frac{3}{4}$ to 1 pound of vegetables, and an equal weight of fruit daily. On such an intake of bulky foods, constipation is rare and no addition of a concentrated residue is needed.

As we have pointed out, there are no analyses of the common foods which state the content of cellulose and hemicellulose. Our analyses of such vegetables as peas, carrots and cabbage suggest that these contain between 2 and 3 per cent of cellulose plus hemicellulose. A pound of such vegetables would contain approximately 10 Gm. of cellulose plus hemicellulose. It is of interest that this amount of indigestible residue was the amount found to be quite effectual in our normal subjects. Finally, we believe that indigestible residues in proper amounts of the *proper chemical composition and finely divided* can do no harm even if taken promiscuously by the general population. Too much emphasis cannot be placed upon the qualitative composition, for we have found residues high in lignin and cellulose but low in hemicellulose, which are frankly constipating and irritating to the rectum. In normal human subjects stools from such substances were passed with difficulty and were blood-flecked. This undoubtedly accounts for many instances of fecal impaction recorded in the literature and the disagreement among clinicians as to the merit of adding residue to the diet.

In the last one hundred years the use of sugar has reached the point where it accounts for 25 to 30 per cent of our calories. The same is true of white flour. Both of these materials are completely absorbed without residue. Before the advent of manufactured sugar and white flour, the ingestion of carbohydrate was invariably accompanied by considerable quantities of cellulose and hemicellulose. We are firmly of the opinion that the best way to take cellulose and hemicellulose is to eat it in the natural state, that is, from vegetables and

whole grain cereals. But we believe that there is a use for concentrated indigestible residues which can be given to individuals who cannot or will not take enough natural foods to obtain bulk. Again, there are others who have mild pathological conditions which would be greatly benefited, symptomatically at least, by giving materials which cause the stool to be more voluminous, pliable and easily evacuated.

CLINICAL EXPERIENCE WITH BEET PULP

One of the basic reasons for our interest in the indigestible residues obtained from agricultural by-products was the hope that we might discover some that would be economically available to the general population. Those materials now put out by the drug houses are very expensive and the great mass of our dispensary patients cannot afford to purchase them. Bran is cheap but in the form that it should be used, namely, when pulverized, it is not widely available, and from the qualitative aspect is far from an ideal material.

Much of the criticism raised against bran and other rough materials is due to the hitherto unrecognized facts (1) that lignin is the material which makes indigestible residue brittle, hard and injurious; (2) that certain indigestible residues are more hygroscopic than others; (3) that the size of the particles of indigestible residues is of great importance, particularly if the residue contains much lignin, or to a less extent, cellulose. The hemicelluloses are so hygroscopic that they can hardly be irritating. If one eliminates those indigestible materials that contain lignin and chooses only materials which are high in hemicellulose and hygroscopic as well, there are no objections to using these indigestible residues even in cases of ulceration of the gastro-intestinal tract. In fact, they are much safer to use than whole vegetables.

Chemically, beet pulp is composed of 34 per cent cellulose and 29 per cent hemicellulose with insignificant amounts of lignin. The ideal indigestible residue, it seems to us, should contain 10 or 15 per cent cellulose and 50 per cent hemicellulose. But of all the products we investigated beet pulp

seemed to us to be closest to this ideal. When it absorbs water, it forms a soft bulky mass similar to that formed by agar. It can be purchased at a very cheap price and is easily washed, dried and ground. We obtained beet pulp from the wholesale dealer, washed it overnight in hot water, dried it in a warm air dryer and ground it fine enough to pass through a 20-mesh sieve. This material is not disagreeable to taste, and by most of our subjects and patients is preferred to bran or agar. When exposed to water, it increases its volume about four-fold.

It has been used by one of us (T. B.) in the gastrointestinal clinic for the past three months. Any case where constipation predominated, whether pathological or functional, was given beet pulp in amounts of 1 or 2 tablespoonfuls a day. We have used it in duodenal ulcers, cholecystitis, so-called "spastic" colitis, hypotonic colon, rectal constipation, mucous colitis, granulomatous stricture of the rectum, gastroptosis, and individuals who have been chronic laxative users. Our experience has not been extensive but the results are more satisfactory than we have obtained by the use of agar or any of the types of emulsified mineral oils. Almost all of the cases were women. We had no control over the actual size of the stools passed, but were dependent entirely on the statements of patients. There is no subject in the field of medicine on which the public is more misinformed than its ideas regarding the normal size of the stool. Why is it that the human race feels that a daily *large* stool is the only satisfactory habit? Those of us who have weighed hundreds of stools of normal people know that some days a normal stool weighs 50 Gm. and other days 250 Gm. But even realizing this ignorance on the part of the average man or woman, nevertheless, the fact that there is the strong instinct for a daily evacuation seems to us a fact that cannot be overlooked. So even though we have not checked the patient's statements by actually weighing the stools, the fact that these individuals taking beet pulp are much more satisfied with their stool evacuation than when they are taking cathartics or mineral oil, seems to us good.

evidence of its efficacy and we believe that the material derived from a vegetable, replacing mineral salts, vegetable cathartics, is a real therapeutic accomplishment. Whether patients will continue to take it day in and day out or whether it will be necessary for them to do so, remains to be seen. Certainly the cost of this material is very little indeed.

In conclusion, we have tried to outline our past work and to give some of the deductions we have arrived at through careful study of the chemistry and behavior of the indigestible residue used in human diets. We have pointed out the characteristics of the ideal type of indigestible residue that can be added to the diet of those individuals whose stools need increased bulk. And it should be emphasized that residue constitutes not so much an addition, but rather a supplement to the diet deficient in normal sources of residue. We have in beet pulp a material which although not quite ideal, is easy to obtain, very reasonable in cost, and thus far in our experience satisfactory in the results that it has given.

CLINIC OF DR. JOSEPH W. LARIMORE

WASHINGTON UNIVERSITY SCHOOL OF MEDICINE

PEPTIC ULCER

THE disease of peptic ulcer cannot be exemplified in all the variety of its manifestations during the progress of the characteristic clinical course by the immediate status of a single case. The following medical history is of an instructive case of peptic ulcer:

The patient is a housewife, aged fifty-six years, who had complained of hyperacidity or heartburn for fifteen years, and had "lived on milk of magnesia and soda." Heartburn had recurred in periods and came on two hours after eating. For the previous six weeks there had been continuous and increasing gastric discomfort, with much eructation having a foul taste, "like bad eggs." There was nausea occasionally, and vomiting once. The weight had been stationary at 140 pounds. Physical strength was good. Sleep was disturbed by gastric discomfort. The pain was general in the upper abdomen, much lessened by taking food, and insistently described as hyperacidity. Without adequate fruits and vegetables in the diet, the bowels were constipated. The stool was natural and there was much intestinal flatulence. The patient had had three children, and had passed a normal menopause. An ovarian cyst had been removed in 1911 and later, because of an obstructed ureter, the right kidney was removed. Constipation began then and increased.

The patient had just returned by automobile from her summer home in the north, and over the week-end prior to examination became acutely worse, with increased general distress, nausea and vomiting.

Physical examination showed a woman of average stature, asthenic constitution, weight 141 pounds, temperature normal, blood pressure 124/88, pulse 92. The ocular and body reflexes were unaltered. The teeth showed many fillings and several extractions, with poor posterior occlusion. The tonsils were moderate in size, ragged and without present inflammation. No glands were palpable. The heart and lungs were normal. The arteries were not palpable. The abdomen was flat, soft and without muscular rigidity or tenderness. There was a low midline operative scar and also one in the right upper quadrant. Visible gastric peristalsis passed from left to right below the umbilicus and there was marked succussion.

Roentgen investigation showed extreme gastrectasia with much retained content, and the pylorus was obstructed. There was a perfect contour to the prepyloric area. After adequate lavage a second opaque meal showed the deformed duodenal bulb and a perfect pyloric isthmus.

Analysis of the aspirated gastric contents showed a 60 per cent (Tophier) free hydrochloric acid and 90 per cent (Tophier) total acid.

Blood study: hemoglobin, 84 per cent; red blood cells, 4,790,000; white blood cells, 10,200.

Urinalysis: specific gravity, 1.035, acid; albumin and sugar, negative; no acetone. Microscopic examination was negative.

Stool analysis was not notable and the guaiac test for occult blood was negative.

The patient was hospitalized and operative interference was anticipated. The immediate treatment consisted in decompression of the stomach by continuous siphonage with a nasal catheter, antacid medication, intravenous glucose and subdermal saline. After the first day, frequent bland feedings were allowed with aspiration of the residue prior to each feeding. Gastric comfort was promptly secured and soon there was evidence, from lessening aspiration, although with larger feedings, that motility was improving. So much improvement occurred in a few days that the operative indication seemed

doubtful. After ten days the patient became ambulatory and returned home. Antacids were continued, diet was increased and living habits restricted to a safely normal amount of activity and rest, with careful regularity.

The subsequent course was one of continued improvement. Roentgenological review showed the stomach of normal size and motility. The patient improved in general health, weight and strength. All discomfort disappeared and the abdomen became normally "silent."

This case illustrates the recurrent periods of duodenal ulcer activity over a period of years with increasing disturbance, generally relieved symptomatically by antacids, until the pyloric embarrassment brought on a chronic stasis. Finally in a period of acute exacerbation, acute edematous swelling stenosed the pylorus completely. Medical treatment corrected this reaction, restored the gastric motility and a regulated manner of living and eating has since maintained this patient in a state of good health.

Peptic ulcer, both the disease syndrome and its characteristic lesion, is wholly a medical condition. Surgery has no place in the treatment of peptic ulcer until some secondary anatomical change has occurred to disturb gastroduodenal function in a fixed manner. It may seem a subtle distinction to speak of the disease of peptic ulcer and its characteristic lesion separately. The conception is, however, extremely important. The healing of the lesion is the immediate and direct interest in treatment, but is not to be confused with cure of the functional disorders which constitute the disease. Neither can surgical attack upon the simple lesion cure the disease. Surgery cannot expect to achieve by any alteration of natural anatomy a restoration of disordered function, which is the basis and not the result of the simple lesion. The symptoms of peptic ulcer are chiefly pain and its associations, and they are due to the lesion and not to the underlying functional derangements. This constitutes a grave danger to the clinical handling of the disease as relief of the pain and the restored comfort may be secured even before the lesion is healed and

certainly before normal function is restored. This relief is erroneously taken as a criterion of cure.

Experimental and clinical studies have arrived at a conclusive justification of the term "peptic ulcer" for the chronic round ulcer which occurs in the stomach and duodenum. The acid pepsin secretion of the stomach accomplishes the excavation and the acid effectively prevents healing, but not unless their physiological regulation is disordered and malconditioned. The gastric secretion in its qualitative characteristics is normally a natural element to the gastroduodenal mucosa, and it follows that some derangement in gastric physiology is necessary to create for the secretions such a dominant place in the development of the ulcer lesion.

The disease of peptic ulcer is fundamentally an alteration in the function of the gastroduodenal segment into an unphysiological status, which permits the development of and, by continuance, maintains the localized lesion of round ulcer, which is in fact only one of the abnormalities of the entire disease. The ulcer lesion is the end-result of the intraluminal chemical conditions produced by the malconditioning of secretion. This unnaturally increased activity of the gastric juice results from varied somatic reflexes and from habit influences. These and their sequence of physiological disorder are the factors which induce the chronicity of round ulcer. The abnormal chemical status allows at the site of an injury, which would otherwise heal promptly by reason of the intrinsic native health of the tissues, the progressive localized destructive excavation of the wall of the stomach by necrosis and digestion, creating according to location either duodenal or gastric ulcer. Healing is prevented by the prolonged secretory activity of the stomach. The failure of the healing processes in the affected tissues are not due to their pathological absence nor to their diminution but rather to interference with their action. The balance between the interference and the native healing varies in each case and accounts for the variations in the lesion and clinical course of ulcer. The fallacy of the conception that the immediate agent or reason for the injury

to the mucosa is also the cause of the continuance and extension of the ulcer lesion has impeded the understanding of other factors and seriously misdirected the efforts of both medical and surgical therapy. It was stated long ago by Cohnheim that "there must be, in addition (to the initial defect) an unknown something which prevents the healing of ulcer." It is therefore necessary to discover in man the influences which, as continuing factors of chronicity, affect the segment and alter its function. Only by correction of these factors can the physiology of the ulcer-bearing segment be restored in the manner to stop an otherwise recrudescient lesion and effect an actual termination of the syndrome.

It is the abnormal conditioning by factors existent in the somatic status, and by the psychic and habit reactivity to extrinsic factors which creates the background for abnormal secretion. Abnormal influences upon the body of the stomach, the pylorus and the duodenum cause a failure in the normal harmony of the activity of the gastric glands and of gastric motility to the needs of digestion. Continuing effective secretion is the intragastric result of the factors of chronicity and is the proved essential of primary peptic ulceration. The classical conception of hyperacidity as strong acid must be modified. A persistent and effective acid-pepsin secretion should be meant, if the term hyperacidity continues to be used. The acid may have a high titer as is usual with duodenal ulcer or may be at a normal level or less as with gastric ulcer. Gastric secretory activity has lost its normal conditioned restriction to the digestive phase of the digestive cycle and there no longer exists the interdigestive period of functional rest for the gastroduodenal segment. It is the prolonged or persistent time factor of secretion which is to be considered as the essential meaning of hyperacidity. Without this abnormally extended time factor of gastric acidity the ulcer lesion and acute injuries to the mucosa will heal. The native reparative faculty of the tissues is unimpaired and its failure is not a factor in the development of the lesion. Healing fails only when hindered by these persisting abnormal influences. It is probable that all

persons frequently suffer such transient mucosal injury with casual or no symptoms. With, however, chronic malconditioning of gastric function the same accident will invite a continuing process of excavation and, when continued acidity of high titer is promoted as in the reflex pyloric syndrome, the cratering process in the duodenum may be initiated without other initial accident to the mucosa. The gastropyloroduodenal reflex hypertonus produces pyloric hypertension, gastric hypertonus, hypermotility and hyperacidity. Duodenitis may result from the vigorous and prolonged bathing of the duodenal bulb by a gastric secretion of high acid titer.

The impairments of gastric function result from the habitual, often unrecognized, violations of the reasonable and accepted requirements of health. These irregularities induce secretory confusion or nonconditioning and abolish the essential normal cycle of gastroduodenal function. Irregularity of eating, indiscreet diet, abuse of condiments, beverages, alcohol, tobacco and confections, with inadequate bodily rest contribute to that end-result. These factors of malhygiene may and often do have associated extragastroduodenal abdominal disease, appendicitis, cholecystitis, colitis and pelvic disease, which reflexly disturb pyloric function. Gastroduodenal hypertonicity with its accompaniment of nonconditioned hypersecretion results. As the hypermotility of the stomach increases and the titer of the gastric content rises, a high acidity is superimposed upon the prolonged time factor. The duodenal bulb is irritated, becomes spastic, and reflux of the neutralizing alkaline duodenal contents is prevented. Gastric ulcer occurs when hypotonicity impairs gastric motility and destroys the normal digestive cycle allowing the continuous activity of the secretions. To be effective in initiating the ulcer lesion any accidents to the mucous membrane must follow upon this functional disorder. These functional disturbances allow continued excavation of the ulcer crater until their correction is secured. This may be achieved by medical management.

Peptic ulcer has a very definite life history, progressing.

although with varying speed, through a succession of pathological changes. The functional derangements succeed, during the life history of the lesion, from first, when the pylorus is only functionally disturbed or the stomach alone is only functionally deranged, to the later stages when the stomach is organically impaired and finally when the pylorus becomes organically obstructed. Progress of the gastric lesion gives increasing callus accumulation, perigastritis and a penetrating crater often enlarging to be an accessory pocket. The duodenal lesion may progress similarly and either lesion may directly or by perigastritis involve the pylorus, causing stenosis by edema, cicatrix or peripyloric involvement. These organic embarrassments of function fix the immediate factors of chronicity beyond any expectation of medical readjustment. They require surgical interference, chiefly for the purpose of restoring motility. Again it may be emphasized that attack upon the organic manifestations of the disease of peptic ulcer is not the correction of the essential factors.

The medical or surgical status of an ulcer may, with our present facilities of investigation of the stomach, be determined adequately. The particular phase of the evolution of the lesion as it is presented for treatment can and should be determined. The recognized facts concerning peptic ulcer may be arranged to present in an analytical perspective the progression in the chronic lesion, which cannot be treated properly upon merely its generic diagnosis as ulcer, but only after its current attributes are understood. It is more important to know of any associated intra-abdominal disease than of focal infection outside the abdomen, and the investigation of the gastro-intestinal tract and of the abdomen must be complete. The surgery of simple chronic ulcer is more likely to be of the appendix, gallbladder or pelvic organs than of the gastroduodenal segment. In many cases, removal of the appendix is necessary and occasionally removal of the gallbladder. The decision for such interference is made with full roentgenological evidence and clinical observation. Medical treatment is indicated so long as the physiological derangements

remain independent of the localized ulcer lesion and direct surgery becomes indicated only when the structural change mechanically fixes the impairments of gastroduodenal function. Medical failure, so-called, can no longer be an adequate surgical indication, although it may often indicate the presence of some organic factor requiring surgery. This, however, must be defined in each case and, until it is, the possibility remains of inadequacy in the manner of medical management as outlined and followed. Surgery may not be done merely because of a sense of medical hopelessness. Also the social, economic and intellectual status of the patient may not constitute an indication for surgical interference when by analysis of the clinical and roentgenological factors, the lesion presents no other surgically removable organic sequelae. Neither does fear of cancer constitute a surgical indication until adequate study discloses definite or ambiguous cancerous characteristics in the lesion.

The medical problem of ulcer is to correct and disestablish the factors which promote the development and progress of the ulcer lesion. Medical treatment is essentially the removal of the factors of chronicity and is directed, first to the healing of the lesion, next to improving the physical status of the patient and finally to curing the disease by restoring and maintaining a properly conditioned and cyclic function to the gastroduodenal segment. The quiescent interdigestive phase of gastric function is essential to healing and must be provided and restored. The lesion of peptic ulcer will heal with the removal of the interfering factor—the continued acid bath of excessive secretion. Neutralization will accomplish this and can be done with the simplest of antacids which may be used adequately, yet adjusted to avoid alkalosis. The accident of alkalosis indicates an indiscriminate excessive use of alkalinizing rather than neutralizing agents. Gastric stasis may be relieved by lavage and prevented by dietetic measures. Diet seeks to meet several contingencies. It should stay within the impaired motor capacity of the stomach and not prolong the digestive period; reduce gastric acidity by avoid-

ance of acid and stimulating foods and by emphasis of bland foods which absorb the secretion; achieve adequate general nutrition; and maintain regularity in the digestive cycles. It is apparent that no single menu can be categorically assigned as the diet of ulcer. Initially the alternation of feeding and antacids, by absorption and counteraction of the gastric secretion, will provide the opportunity for healing of the lesion. This will be prompt under such favorable conditions. Treatment of the lesion by an ambulatory régime will avoid the implication that the relief of pain and other symptoms by the same care during a relatively brief period in hospital is the cure of the disease. After the lesion is healed or definitely started toward that end the essential restoration of the functional status of the gastroduodenal segment must receive continued attention. This entails a careful rearrangement of the patient's habits of living, and may be achieved best with the ambulatory régime. Although the ulcer lesion may heal promptly, the functional disturbances which constitute the disease of ulcer show a dominant tendency to persist and to exaggerate with unfavorable hygienic and health episodes. Reconditioning of secretion may be accomplished easily, in the absence of reflex interference of extragastric intra-abdominal disease. A vacation may allow it, but return to old habits of work and living will as easily reinstate the confusion of function. Reconstruction of the patient's habits of life must be secured in some permanent manner. Since the whole of the patient and the manner of his life must be considered, very serious doubt is cast upon the claims of any of the forms of specific ulcer therapy now in vogue. Upon the premises outlined above for the genesis of ulcer it is difficult to conceive of a conclusive restoration of normal physiology being established by any manner of injection therapy or specific oral administration regardless of their effects upon autonomic balance or tissue reactivity. These specific remedies are in the main urged for the healing of the lesion.

The accidents of ulcer, perforation or hemorrhage, are neither inevitable nor usual steps in the life history of ulcer.

Perforation to peritoneal surfaces requires immediate surgical interference. Delay is disastrous. Hemorrhage remains a medical problem unless associated to some anatomical sequelae of the simple ulcer lesion. Hemorrhage occurs from the opening of a vessel by reason of the excavating activity in the ulcer lesion. Hemorrhage can be treated best by prompt introduction of measures to permit the reparative processes to be effective—by control of acid peptic activity with antacids and selected food. Extended fasting and narcotics leave the abnormal secretory factors of the ulcer process uncontrolled. This counteracts the normal hemostatic reactions at the bleeding point. Surgery is indicated when the activity of the ulcer is encouraged by organic complications. Repeated hemorrhage may indicate in fact such a status but this should be demonstrated before recourse to surgery.

With ideal medical treatment, to which there are many obstructions, simple chronic ulcer will not advance into surgical complications. Medical diagnosis is improving and advancing the recognition of ulcer. Medical management is gradually freeing itself from the classical régime predicated upon the late, originally described, status of ulcer which has already advanced into a surgical condition. Treatment is now based upon the factors involved in the genesis of the disease and development of the lesion. Surgical technic continues to achieve more successful correction of the complicating sequelae of the ulcer lesion. It is incumbent upon the physician to determine the transition or the status of ulcer with some fixed anatomical factor of chronicity which requires surgery.

CLINIC OF DR. WENDELL G. SCOTT

THE EDWARD MALLINCKRODT INSTITUTE OF RADIOLOGY.
WASHINGTON UNIVERSITY SCHOOL OF MEDICINE

THE DIAGNOSIS OF THE STONELESS GALLBLADDER

THE term "stoneless gallbladder" includes acute cholecystitis which may or may not develop into an empyema or hydrops of the gallbladder; chronic cholecystitis; cholesterosis (strawberry gallbladder without stone); typhoid carrier's gallbladder; and papillomas of the gallbladder. In general it may be said that, with the exception of acute cholecystitis, the most difficult problem for the physician when dealing with these patients is in the establishment of the correct diagnosis.

The importance of recognizing the stoneless gallbladder is well appreciated by reviewing its high incidence. Graham, Cole, Copher and Moore¹ in their book concluded that 24 per cent of the adult population have gallstones and that an equal number have cholecystitis without stones. This suggests that 20 to 24 per cent of the adult population have potential stoneless gallbladders which may give rise to active symptoms at any time. The first sentence in a new book on the gallbladder by Rehfuess and Nelson² reads, "We now realize that gallbladder disease is the commonest cause of upper abdominal trouble." In 612 routine postmortem examinations at the Mayo Clinic Mentzer³ found pathological evidence of cholecystic disease in 66 per cent of the cases. Only 8 per cent of the 612 patients had a primary diagnosis of cholecystitis which indicates that a large number of people afflicted with gallbladder disease may have very few, if any, symptoms.

ACUTE CHOLECYSTITIS

Acute cholecystitis with and without stones occurred only 7.6 per cent of 848 cases¹ of gallbladder disease in the Barnes Hospital, and it may be safely said that the number without stones constituted a small fraction of this per cent.

The symptoms in acute cholecystitis are sufficiently characteristic so that the diagnosis can be made from the history and physical findings. The onset is usually sudden, sometimes with a chill. The attack begins in the epigastrium or right upper quadrant. The pain is excruciating or only moderately severe and may radiate to the angle of the right scapula. Ordinarily, the pain begins to subside in twenty-four to forty-eight hours and after a week or ten days the symptoms are gone. In noncalculous cholecystitis the pain is less severe and rarely colicky in nature. The fever is not high (100° - 102° F.), and the leukocyte count averages between 10,000 and 18,000. Physical examination reveals local tenderness, rigidity, enlargement of liver, and occasionally the palpable mass of a large, tense gallbladder.

The value of a detailed film of the gallbladder region is slight, but is helpful in ruling out a renal colic from stone or in demonstrating positive gallstones. Cholecystography is of great help in perfecting the diagnosis, but should be withheld until the acute symptoms have subsided.

The occurrence of jaundice following these symptoms results from an inflammatory obstruction of intrahepatic ducts from edema, infiltration with leukocytes, etc., as shown by Graham.

The pathological changes vary from a mild redness of the mucosa to an extensive inflammatory infiltration of all the layers of the gallbladder wall complicated by hemorrhage, necrosis, or even gangrene. As the result of a partial blockage of the cystic duct by inflammatory debris or a stone the accumulated contents may develop into a hydrops (if non-purulent), or an empyema (if purulent) of the gallbladder.

CHRONIC CHOLECYSTITIS

A majority of all cases of dyspepsia can be attributed to the chronically diseased gallbladder. Its manifestations are protean and extremely variable in intensity. The progress of most cases is notoriously slow. Alvarez reports that the average duration of symptoms was nineteen years.

The etiology of chronic cholecystitis without stones is uniformly attributed to infection by any one of many different organisms of different virulence. The mode of infection¹ can conceivably occur by: (1) descending infection from the liver by bacteria carried down in the bile; (2) ascending infections from the duodenum up the common bile duct; (3) hematogenous infections of the vesicle and ducts; (4) a spreading of infection to the wall of the gallbladder from the liver or an inflamed contiguous organ. The work of Graham and Peterman shows that routes 3 and 4 are the most likely.

Another type of chronic gallbladder disorder is that termed cholesterosis (strawberry gallbladder). Here yellow particles of an ester of cholesterol are present on the red mucosa giving an appearance resembling a ripe strawberry. A review of the literature shows that there is not an unanimity of opinion as to whether cholesterol is absorbed or excreted by the wall of the gallbladder to produce this condition.

Cholecystitis occurs twice as frequently in women as in men. Obesity, multiple pregnancies and middle age are definite predisposing factors.

The most reliable and consistent symptom of chronic gallbladder disease is recurrent indigestion with flatulence usually accompanied by mild pain and discomfort in the epigastrium or right upper quadrant. After a large meal, especially one with fats, these patients suffer with "bloating," upper abdominal distention and fullness, and seek relief by belching. Patients with infected gallbladders are frequently troubled by persistent constipation and become addicted to laxatives. Rheumatic and arthritic complaints are common associates. Nausea, vomiting, referred shoulder pain, deranged nervous

and cardiovascular systems may enter the picture to obscure the more common complaints.

Laboratory procedures are frequently the only means of obtaining the correct diagnosis. Of these the most reliable and universally accepted test is cholecystography. The Meltzer-Lyon technic for biliary drainage by duodenal intubation is a most helpful aid in diagnosis and in experienced hands is very accurate. Examinations of the stools, blood and gastric contents may be helpful in a differential diagnosis. A careful gastro-intestinal x-ray examination should be performed in all cases because the symptoms produced by cholecystitis, gastric malignancy, duodenitis and peptic ulcer may make a differential diagnosis difficult. Furthermore, cholecyctic disease is not uncommonly associated with peptic ulcer and appendiceal diseases, the recognition of which requires study with the opaque meal.

In a fascinating study on the evolution of the radiographic diagnosis of gallbladder disease Sherwood Moore⁴ points out how an x-ray diagnostic accuracy of only 30 per cent was raised to an efficiency of 97.2 per cent by the advent of cholecystography (the Graham-Cole test). There was also a large increase in the total number of pathological gallbladders detected. This increase was composed largely of the stoneless gallbladders and those with cholesterol or negative stones.

From these facts concerning cholecystitis without stones it is evident that: first, a large part of the population are affected; second, the symptoms may be severe but are usually vague; and third, cholecystography is the most reliable single procedure in its diagnosis.

The reliance placed on the cholecystographic diagnosis of the stoneless gallbladder requires a thorough understanding of this test. Graham has written that cholecystography is fundamentally a physiological test of the function of the gallbladder, liver and biliary tracts. Certain conditions are necessary for satisfactory visualization:¹

1. The dye must get into the blood stream in a sufficient amount.
2. The dye must be excreted by the liver into the bile.
3. It must reach the gallbladder. This necessitates patent hepatic, cystic and common ducts.
4. The patient must be fasting in order that the sphincter of the common duct can divert the bile through the cystic duct into the gallbladder.
5. The gallbladder wall must be sufficiently normal to concentrate the dye.

A single defective link in this chain of events results in either faint visualization or nonvisualization.

The following is a brief description of the technic for intravenous and oral cholecystography used at the Edward Mallinckrodt Institute of Radiology.⁵ The intravenous administration of the dye is preferred to the oral method because, in our hands, it gives more accurate results; it permits a liver function test; it produces fewer reactions and, most important, a known quantity of the dye reaches the blood stream. The oral method, however, is simpler, less expensive and quicker. It is ideally adapted for the routine investigation of the gallbladder in patients receiving a gastro-intestinal series who do not present predominant clinical features of gallbladder disease. The problem of choosing between these two methods resolves itself largely into a matter of individual opinion and applicability.

Intravenous cholecystography is directly applied to practically all patients whose symptoms and findings primarily suggest gallbladder disease. A preliminary open film of the gallbladder region is routinely taken on the day preceding the intravenous injection. If gallstones are unquestionably visualized the patient's physician is notified and the injection is cancelled.

Ampules of phenoltetraiodophthalein sodium are prepared in the Barnes Hospital pharmacy to insure the use of fresh solutions. In the preparation of intravenous solutions too much emphasis cannot be placed upon the necessity of using

absolutely clean glassware and freshly distilled water of known purity. Extreme care should be used in washing the containers, syringes, etc., free of lysol or other antiseptics which may drain into them from the sterile instrument used in their handling.

For adults the dosage is 2.5 Gm. (38 grains) of phenol-tetraiodophthalein sodium for patients weighing 138 pounds

Fig. 32 - Set-up for intravenous administration of phenoltetraiodophthalein sodium showing gravity flask containing 25 cc. of warm sterile saline solution (0.9 per cent). About 20 cc. of saline must first run in freely to verify the position of the needle within the vein

or over. Proportionately smaller doses are given to patients weighing less. In the preparation of a single ampule 2.5 Gm. of phenoltetraiodophthalein sodium (iso-iodeikon) are dissolved in 30 cc. (1 ounce) of hot triple distilled CO_2 free water. The solution is filtered through five layers of fine filter paper and placed in a glass ampule which is sealed in the gas

flame and then sterilized in a boiling bath for twenty minutes. An ampule prepared in this manner can be safely used within a period of three weeks.

The only preliminary preparation necessary for intravenous cholecystography is that the patient receive no fluids or food after midnight on the day preceding the injection. The following morning breakfast is omitted and the dye is injected at 9 A. M. The technic of the administration is illustrated in Figs. 32, 33.

Fig. 33.—The glass syringe containing 30 cc of phenoliodophthalein sodium solution (1 ampule) is shown inserted into the rubber tubing after first sterilizing the outside of the rubber tube with alcohol. The mixture of the sterile saline solution and dye is observed by the operator as it flows through the glass adaptor fitted to the needle puncturing the vein; thus the rate of injection of the dye can be absolutely controlled and stopped with the appearance of any toxic symptoms without interrupting the flow of saline. Fifteen minutes are required for the injection of the dye. Sufficient saline is run in after all the dye has been injected to wash out the vein.

The films are made in the prone position four, eight and twenty-four hours after the injection. The gallbladder should be definitely visualized on the first film. At eight hours the shadow should have altered in size and increased in density. This capacity to alter in size is considered a measure of the elasticity of the gallbladder wall. The increased density is due to the concentration of the dye resulting from the absorption of water by the intact and functioning mucosa of the vesicle.

After the second film the patient may have food and drink including supper and breakfast. A special fat meal is not considered necessary. The final film is taken the next morning, when the gallbladder shadow has normally disappeared or has decreased considerably in size and density, demonstrating the ability of the vesicle to empty. If the gallbladder fills, concentrates the dye, alters in size and empties, as described above, it is considered normal. Nonvisualization of the gallbladder means a diseased (pathological) gallbladder. A faint gallbladder shadow indicates an impairment of the concentrating function and is somewhat proportional to the degree of pathology present. This is a treacherous sign and demands considerable experience in the viewing of cholecystograms. Sherwood Moore⁶ has prepared an excellent summary on the radiological interpretation of cholecystograms.

For the liver function test 12 cc. of blood are removed exactly thirty minutes after beginning the dye injection. The blood is placed in a clean test tube, allowed to clot, the serum alkalized and compared colorimetrically with known standards.

The capsule method as formulated by Larimore is employed routinely for oral cholecystography. The individual dosage by mouth is 4.7 Gm. (72 grains) of tetraiodophenolphthalein. It is thoroughly mixed with 0.8 Gm. (12 grains) of pulverized agar and the mixture put into 6 stearic acid-coated capsules, 00 size.

The stearic acid serves to prevent the dissolution of the capsules by the gastric juices. As a further precaution one heaping teaspoonful of baking soda is given about thirty minutes prior to taking the capsules to increase the alkalinity of the intestines. The dye thus passes into the duodenum without being converted into the insoluble acid tetraiodophenolphthalein. The stearic acid coating is digested by the alkaline intestinal juices and, as the powdered agar becomes moistened, it swells and tends to prevent "caking" of the dye. The dye is carried to the liver by the portal circulation where it is excreted in the bile. The gallbladder shadow is produced

in the same manner as described under the intravenous method.

No preliminary preparation for oral cholecystography is necessary and it is preferable that the patient have the regular evening meal. At 7:30 P. M. the patient takes the soda in a half glass of water. Then, within the hour of 8 P. M. and 9 P. M. all 6 capsules are taken with as little water as necessary to swallow them. Food and drink except for small amounts of water are prohibited and breakfast is omitted.

Roentgenograms are made twelve, fifteen and eighteen hours following the ingestion of the capsules. After the second film the patient has the regular noon meal.

Any adequate visualization of the gallbladder without abnormalities of position, size, contour, or content (stones or papillomas) is considered normal. Very faint shadows or non-visualization associated with reactions, as severe diarrhea or early vomiting, is classed as indeterminate because loss of the dye vitiates the results. This occurs in a minimal number of cases and the test is repeated, preferably by the intravenous method.

Reactions have caused no significant inconvenience to the patients, who rest in a horizontal position for one-half hour after the injection as a precautionary measure. Hypodermic injections of 4 to 8 minims of adrenalin controlled urticaria and reactions simulating circulatory shock. Abdominal cramps and diarrhea following oral administration of the dye are best treated with codeine and paregoric.

The only definite contraindications for intravenous or oral cholecystography are severe cardiac disease and patients with very low blood pressure. From a physiological viewpoint patients with acute liver infections, common duct obstruction or acute yellow atrophy of the liver, should not be submitted promiscuously to cholecystography. In patients with jaundice of any type the gallbladder is rarely visualized. The test should be deferred with patients having high fever, severe cachexia, or marked dehydration.

While cholecystography is invaluable in the diagnosis of

stoneless gallbladders it should be emphasized that a pathological cholecystogram is not a sufficient reason for cholecystectomy. Several writers have called attention to the unsatisfactory results following cholecystectomy on patients whose gallbladders revealed only minimal changes. Graham and Mackey⁷ report that "In the absence of severe pain the beneficial results to be obtained by cholecystectomy in cases of a stoneless gallbladder are likely to be unsatisfactory in approximately 40 per cent." The determination of how much a patient's symptoms are due to the gallbladder in a case of minimal disease necessitates an extremely thorough study for sources of other trouble before resorting to operation. It is well to remember that cholecystitis without stone is a disorder the severity of which varies widely and includes the borderline area between functional and organic disease. Kirklin and Blake⁸ point out that "However valid the cholecystographic signs of impaired function may be of disease of the biliary tract, they will not determine whether the disorder is transient or chronic, mild or severe, or whether it is the cause of the patient's chief complaint, and determination of these matters rests solely with the clinician. In short the roentgenologist and the clinician are obliged to cooperate."

SUMMARY

In spite of the widespread occurrence of cholecystitis without stone there is no lesion in the abdomen that requires a more painstaking study of the patient's history and cholecystograms. Such an illusive diagnosis must be confirmed further by the differential elimination of other disorders in the abdomen.

The author expresses his appreciation to Dr. Sherwood Moore and Dr. Glover H. Copher for their help and suggestions.

CLINIC OF DR. ALFRED GOLDMAN

BARNES HOSPITAL

DIAGNOSIS AND TREATMENT OF PULMONARY BLEEDING

PULMONARY bleeding is one of the most important symptoms of pulmonary disease and certainly the most striking to the patient. For the proper handling of a case of pulmonary hemorrhage, it is essential first of all to make a correct diagnosis. While the majority of cases of pulmonary bleeding is due to tuberculosis, careful study has shown that many cases have been erroneously diagnosed. The routine use of lipiodol and bronchoscopy in doubtful cases has been particularly valuable. In this discussion the chief consideration will be that of bleeding from the lungs and bronchi.

From the standpoint of diagnosis it is important to distinguish between hemoptysis and hematemesis. This is usually easy but there are times when blood from the lungs is swallowed and more rarely vomited blood may be aspirated and then coughed up. The history of previous or subsequent pulmonary trouble is important. In the absence of a suggestive history, as when hemoptysis or hematemesis occurs as an initial symptom, the character of the blood is important. Pulmonary blood is usually frothy, bright red in color, alkaline in reaction, the coagula are usually small and there may be mixed mucopus. Gastric blood is usually dark, clotted, may be mixed with particles of food and is often acid in reaction. The patient usually turns pale and may faint and then has hematemesis, while in hemoptysis the bleeding occurs first and then pallor and faintness ensue.

Local conditions in the nose, throat and larynx must always be considered in supposed cases of pulmonary bleeding. These are more properly taken up by the rhinolaryngologist but should be mentioned here. The *nose* may be the seat of epistaxis. In the *mouth*, a gingivitis may be the source of the blood. Adenoids occasionally bleed. In the *pharynx* peritonsillar abscess and varicosities at the base of the tongue may cause profuse bleeding. In the *larynx* the following conditions may cause bleeding: luetic, tuberculous and malignant ulcers, injuries, varicosities, angioma and any acute laryngitis. In the *trachea*, luetic or malignant ulcers, foreign bodies, varicosities, congestion from pressure of an aneurysm, an enlarged thyroid or tumor, irritant gases such as chlorine or mustard.

Practically all of the above mentioned causes for bleeding may be directly visualized by the laryngologist and bronchoscopist.

Bronchopulmonary bleeding may be classified as follows:

(A) Diseases of the lungs and bronchi:

1. Pulmonary tuberculosis,
2. Bronchiectasis,
3. Broncholithiasis,
4. Pulmonary abscess,
5. Pulmonary gangrene,
6. New growths,
7. Injuries of the lung,
8. Pneumonia,
9. Pneumoconiosis,
10. Fungus infections,
11. Foreign body,
12. *Fusospirochetosis*.

(B) Diseases of the heart and vessels:

1. Mitral stenosis,
2. Thromboses and emboli from cardiac disease,
3. Emboli from phlebitis,
4. Aortic aneurysm rupturing into the lungs, bronchi or trachea.
5. Hypertension.

(C) Diseases of the blood.

(D) Vicarious menstruation.

(E) Hemoptysis in the healthy.

(A) DISEASES OF THE LUNGS AND BRONCHI

1. **Pulmonary Tuberculosis.**—Every case of frank pulmonary bleeding should be considered as pulmonary tuberculosis unless proved otherwise. There are three types of bleeding in tuberculosis. In the early stage, the hemorrhage is usually caused by a local inflammatory hyperemia, the amount of blood is small, usually mixed with sputum. Later, as softening of the lung takes place, small vessels may be invaded and rupture takes place. This may give rise to a profuse hemorrhage. In the last or cavitation stage, the severest type of hemorrhage occurs due to rupture of a miliary aneurysm in the wall of a pulmonary artery. If this lies in a large cavity, fatal hemorrhage may take place. This fortunately is rare and recovery may take place from the severest type of hemorrhage in tuberculosis. Fishberg states that less than 2 per cent of bleeding consumptives die from hemorrhage directly.

The diagnosis of tuberculosis is usually obvious. The previous history, past and family, the physical examination, study of the sputum, x-ray are all of equal value. It must be remembered that with severe bleeding, very little examination may be possible and accurate diagnosis may have to be deferred. In doubtful cases, a tuberculin test may be of value, especially when negative. The age of the patient is of value, hemorrhage in tuberculosis occurring in the young and middle-aged. There is a definite small group in which the findings are so minimal that only subsequent developments can assure the diagnosis. These cases must be considered as tuberculosis in the absence of some other satisfactory explanation. Other diagnostic features will be taken up in the consideration of other causes of bleeding.

2. **Bronchiectasis.**—Hemorrhages are very common in bronchiectasis, occurring in 50 per cent of the cases. The blood is usually well mixed with sputum but in some cases, there may be severe bleeding, practically never fatal, however. Differentiation from tuberculosis is usually easy. The site of the bronchiectasis is usually basal but the occasional case of apical bronchiectasis will be confusing and more diffi-

cult of differentiation from tuberculosis. The study of the sputum is the chief differential point. The routine use of lipiodol is indicated in all cases of pulmonary bleeding where diagnosis is obscure and where the necessary manipulation of the patient in introducing the lipiodol will not be harmful. Often bronchiectatic areas which have been completely overlooked by physical examination and x-ray have been visualized with oil. This is particularly true in cases where the diseased lung field is covered by the heart shadow. It must be remembered that bronchiectasis is common in pulmonary tuberculosis. Many of our bronchiectatic cases have been bronchoscoped for direct visualization of bleeding areas.

3. **Broncholithiasis.**—The most common symptom of broncholithiasis and pneumolithiasis is bleeding. Bleeding is usually mild but at times may become fairly severe. It is rarely fatal. The blood may precede the coughing up of a stone or may occur without the expulsion or may follow the stone. One of my patients who has coughed up approximately 25 stones in the past three years was able to foretell the passing of a stone. The initial symptom was pain in the anterior chest. This was followed by a rather profuse hemorrhage and then a stone would be coughed up. Shortly after the expulsion, the patient was free of all symptoms and remained asymptomatic until the next attack. The diagnosis is, of course, dependent on the history, but one must question the patient specifically about the presence of "stones" in the sputum. A tentative diagnosis may be made on the basis of numerous calcifications seen in the x-ray plate. There are occasional cases in which no broncholiths are visible in the x-ray. Stones have been expelled following induction of artificial pneumothorax in cases where no stones had been previously expectorated. Lipiodol may show the presence of a blocked bronchus. Bronchoscopy may show the stones in the bronchial lumen or perforating into the bronchus and the stones may be easily removed.

4. **Pulmonary Abscess.**—Abscess of the lung often shows bloody sputum usually well mixed with pus. Frank bleeding

may be present. The diagnosis is based on the symptoms of a pyogenic infection, fever, cough and foul purulent sputum. The physical signs are those of cavity but are not readily made out unless the abscess is large and close to the periphery. The x-ray shows a rarefaction with a fluid level. Apical abscess may be difficult to differentiate from tuberculosis. The sputum examination for tubercle bacilli is important. Elastic tissue is present in lung abscess. Clubbing of fingers is common in pulmonary abscess. Lipiodol may be necessary to distinguish from bronchiectasis. Lung tumors may be secondarily infected and give symptoms of lung suppuration.

5. **Pulmonary Gangrene.**—Bleeding in gangrene varies from a small amount of blood to very large hemorrhages. Indeed, fatal hemorrhages are not infrequent. The diagnosis is based on the symptoms of cough and sputum of very offensive odor. Large amounts of lung tissue may be expectorated. Most cases progress to a rapid death, although an occasional one survives.

6. **New Growths.**—Cancer of the lung is one of the most common causes of hemorrhage in people past fifty. Bleeding may be absent, may be slight and may appear as blood streaks, or there may be a profuse but rarely fatal hemorrhage. The diagnosis is based on the symptoms of pain in the chest, dyspnea and hemoptysis in a person past middle life; the presence of a more or less characteristic mass on physical signs and x-ray; a pleural effusion which may contain malignant cells; the presence of malignancy elsewhere; the presence of atelectasis as evidenced by the use of lipiodol; the bronchoscopic evidence of tumor; the presence of tumor tissue in expectorated sputum; thoracoscopy may directly visualize a tumor and finally, an exploratory thoracotomy may be necessary for diagnosis.

7. **Injuries of the Lung.**—Any severe trauma to the chest wall may cause mild or severe pulmonary bleeding. Those cases in which fractured ribs puncture the lung are quite obvious. Severe bleeding may occur following blows without

fracture. In such cases, the possible inciting of an old tuberculous process must be considered, though undoubtedly bleeding may take place from the normal lung. Spontaneous pneumothorax may produce pulmonary bleeding particularly if the lung is torn. Hemorrhage may occur after attempted paracentesis of the pleural cavity.

8. **Pneumonia.**—The early sputum in lobar pneumonia is blood-streaked and later becomes rusty. Occasionally pneumonia may start out with a brisk hemorrhage. In bronchopneumonia of the influenzal type frank blood is often present in the sputum. The diagnosis is usually easy although tuberculosis must always be kept in mind.

9. **Pneumoconiosis.**—This condition is very rarely a cause for hemoptysis. Occasionally cavities occur in anthracosis which might produce bleeding. Bleeding is seen in chalicosis. The severe types of hemorrhage are usually associated with secondary tuberculosis.

10. **Fungus Infections.**—Actinomycosis, aspergillosis and streptothricosis cause chronic lung suppuration and may produce bleeding. This is usually an important symptom.

11. **Foreign Body in the Lung.**—This may cause immediate bleeding, particularly if the foreign body is nonorganic. Any foreign body may produce bloody sputum as pulmonary suppuration develops following blockage of a bronchus. Diagnosis depends on the history of a foreign body, symptoms and physical signs of obstructive breathing and bronchoscopy. The latter is very important and should always be done even in doubtful cases. Lipiodol may be done prior to bronchoscopy and may show an obstructed bronchus.

12. **Fusospirochetosis.**—Bronchopulmonary spirochetosis may cause blood-streaked sputum or mild hemoptysis. The diagnosis is made on the finding of fusiform bacilli and spirochetes in large numbers in the sputum. These organisms are often present in small numbers, as secondary or nonimportant organisms in chronic lung disease.

(B) DISEASES OF THE HEART AND VESSELS

Mitral lesions very commonly cause hemorrhages. Some observers feel that it is probably second only to tuberculosis as the most common cause of pulmonary bleeding. While hemorrhages are usually slight, coming by diapedesis or rupture of capillaries, at times very severe paroxysmal pulmonary hemorrhages may occur.¹ Death from hemorrhage may occur in mitral stenosis. Infarcts form and produce dense shadows in the lung which may be difficult to differentiate from pulmonary tuberculosis. It is a well-known fact that patients with mitral stenosis often find their way to a tuberculosis sanatorium because of the bleeding. The diagnosis is dependent on a careful examination of the heart. The characteristic murmurs may be absent when the heart is rapid and a flutter or fibrillation may be overlooked. The dense shadows sometimes seen in the lung picture in mitral stenosis following hemorrhage disappear quickly and completely with improvement. Pulmonary tuberculosis is extremely rare in mitral stenosis.

Thrombi and emboli from cardiac disease and emboli from other sources cause hemorrhages of varying degrees. An infarction may be present without hemoptysis. The diagnosis of infarction is based on the history of probable presence of emboli, sudden pain in chest, dizziness, hemorrhage and physical signs of infarction. A large infarction is immediately fatal. In the lesser bleeding of cardiac congestion heart failure cells are usually found in the sputum.

An aortic aneurysm may produce seepage of blood into the bronchopulmonary tract and cause frequent bleeding. The sudden rupture of the aneurysmal sac into the lungs or bronchi causes severe hemorrhage with immediate death, a common ending in aortic aneurysm.

Occasionally, bleeding occurs from the lungs in cases of hypertension in which there is no evidence of tuberculosis. This may be due to congestion or infarction.

(C) DISEASES OF THE BLOOD

Purpura, pernicious anemia, scurvy, hemophilia, leukemia, all may produce hemoptysis. Bleeding, however, is unimportant in these cases.

(D) VICARIOUS MENSTRUATION

It is a well-known fact that tuberculous women are apt to spit blood during the menstrual period. Occasionally non-tuberculous pregnant women have periodical pulmonary hemorrhages which cease following childbirth. At times, apparently healthy women have severe hemorrhages during menstruation.

(E) HEMOPTYSIS IN THE HEALTHY

Pulmonary bleeding may occur in young healthy individuals without any apparent explanation. Bleeding may recur from time to time. Many of these cases have been followed for years without developing any pulmonary lesion. Tuberculosis must be carefully considered.

TREATMENT OF PULMONARY BLEEDING

Mild hemorrhages require no special treatment other than that of the underlying condition. In all cases of pulmonary bleeding, the patient should be reassured that it is in itself of little significance. There is considerable truth in the statement that if the patient survives the immediate effects of the hemorrhage, the prognosis from the standpoint of blood loss is good. As stated above, pulmonary bleeding very rarely causes death. However, there is much to be gained by the proper handling of a case. It is, of course, extremely important to make a proper diagnosis. Since severe bleeding contraindicates any extensive examination, diagnosis may be delayed and treatment instituted without exact knowledge of the kind and site of the bleeding lesion. It must be emphasized that pulmonary hemorrhages often stop spontaneously, so that the apparent excellent therapeutic effect of any of the numerous methods used must be interpreted with caution.

1. **General Methods.**—Absolute bed rest is indicated, but the patient should be put and kept in a semireclining position so as to facilitate the expulsion of blood and sputum. The patient is usually very apprehensive and should be calmed and assured that the hemorrhage is not serious and will soon stop. He should be encouraged to bring up the secretions in the bronchial tubes gently and with little expulsive effort. He should be allowed to move quietly in bed but not to the complete sitting position. An ordinary chest binder may help reduce the cough. The period of rest is dependent entirely on the cause of bleeding.

The use of morphine has long been a mooted question. To snore the patient under and allow him to retain blood clots and sputum is to encourage aspiration pneumonia, atelectasis or spread of the pathologic process present. However, morphine produces rest of the body, peace of mind and allays excessive cough. Severe coughing obviously encourages renewed bleeding. It is best, therefore, to give codeine first, and if this is insufficient a small dose of morphine, preferably $\frac{1}{6}$ grain, may be given. It is usually unwise to repeat the morphine. Sodium bromide is of value in 5-grain doses.

An ice-bag to the chest is a measure of reassurance to the patient, but probably has no other real value. Swallowing of small bits of ice is usually advised.

Binding of the limbs, the arms and legs for one-half to two hours with a tourniquet and then slowly loosening the tourniquet may be of value. This is supposed to increase the thrombokinas in the blood and encourage blood coagulation.

The diet is important during bleeding. The patient should be starved for a few hours. A soft diet should be used with limitation of ingested fluids. Hot foods, tea, coffee and alcohol are contraindicated. A regulation diet may rapidly be resumed several days after cessation of bleeding.

Artificial Pneumothorax.—In pulmonary tuberculosis artificial pneumothorax is our most effective measure when other simpler methods have failed. It is, of course, necessary to know from which side the hemorrhage is coming. This may be very

difficult as the tuberculous lesion may be bilateral. The patient's symptoms, the physical signs, and the x-ray are helpful in the localization. In cases where it is impossible to localize the site, pneumothorax may be induced on the most likely side. Some maintain that even if the wrong side is collapsed, a favorable effect is produced on the bleeding lung. When pneumothorax is technically impossible because of adhesions, other forms of collapse therapy may be used. Phrenicectomy in conjunction with artificial pneumothorax has been of value. Plombage may stop the hemorrhage coming from an apical cavity. Finally thoracoplasty may be necessary to control hemorrhage in tuberculosis.

In nontuberculous lesions collapse therapy may also be indicated. We have stopped hemorrhage in cases of bronchiectasis and lung abscess by artificial pneumothorax. We have had a striking instance of cessation of bleeding in bronchiectasis by phrenicectomy. We have had the interesting experience on several occasions of the expulsion of an unsuspected broncholith following artificial pneumothorax for bleeding. There are certain cases of undiagnosed pulmonary bleeding in which one may be justified in inducing a pneumothorax for symptomatic relief. The compression may be immediately effective and continue so long as the lung is collapsed.

Bronchoscopy.—Bronchoscopy is of considerable value in the diagnosis and treatment of pulmonary bleeding. It should be used routinely in all cases of undiagnosed pulmonary hemorrhage unless there is some special contraindication. As a therapeutic measure it is of particular value in cases of foreign bodies, broncholiths and endobronchial tumors. The bronchoscopist may be able to directly treat bleeding areas in the tracheobronchial region. He may indirectly influence hemorrhage by his treatment of lung abscess and bronchiectasis. Bronchostenosis may be favorably affected.

Lobectomy and Pneumonectomy.—This special operation is indicated not because of bleeding in itself but because of the underlying lesion. Lobectomy is the operation of choice in bronchiectasis. In carcinoma of the lung it is the only

method of cure except in those rare cases in which an early endobronchial tumor may be satisfactorily removed by the bronchoscopist. Removal of an entire lung for carcinoma has been successful.

2. Methods to Reduce Blood Flows and Increase Coagulation.—There are many drugs which have been advocated for pulmonary bleeding. The purpose of the drug is either to reduce the pulmonary blood flow or to increase the coagulability of the blood. It must be said that in spite of enthusiastic support on the part of many, most of the drugs are probably valueless. However, they should be mentioned.

Salt.—The swallowing of a tablespoon of common table salt dissolved in a glass of water is a time-honored remedy. This is said to increase the coagulation of blood. The salt may be injected intravenously, 5 cc. of a 10 per cent solution may be used, 10 cc. of a 10 per cent calcium chloride solution may be used for the same purpose.

Emetine.—This may be used hypodermically in $\frac{1}{2}$ - to 1-grain doses in place of ipecac. It is supposed to act as a hemostatic. Its value is doubtful.

Ergot is a very popular remedy but it actually causes a rise in the pulmonary blood pressure and should not be used.

Digitalis raises blood pressure in the pulmonary artery and is therefore theoretically harmful.

Aconite produces a definite fall in the pulmonary blood pressure and may be of value.

Pituitary extract while raising the systemic blood pressure lowers the pulmonary blood pressure. It may be used in protracted cases.

Atropine may be given hypodermically in $\frac{1}{100}$ -grain doses with apparent benefit.

Congo red given intravenously was first advocated by Becker.² He gives 10 cc. of a 1 per cent solution intravenously. It is supposed to reduce clotting time, increase the blood platelets and blood fibrin content.

Ammonium tartrate is strongly recommended by Maltei and Escudies.³ It is given daily in 10-Gm. doses for five days.

x-Ray of the spleen is advocated by Neddermeyer⁴ who states that it hastens blood coagulation.

Adrenalin by mouth and subcutaneous injection has been extensively used with doubtful results. Ascoli⁵ has recently advocated a method by Dr. Guiffrida in which adrenalin is injected directly into the bronchi by the intratracheal supraglottic route. Three cc. of a $\frac{1}{1000}$ solution of adrenalin diluted with 2 cc. of water is used and may be repeated in twelve hours.

Intratracheal injection of water is highly recommended by Pennetti⁶ who states that it causes a reflex vasoconstriction and stops hemorrhages in the majority of cases.

Camphorated oil in hypodermic form, 5 to 10 cc. of a 25 per cent solution, is highly recommended and apparently stops hemorrhage.

Parathormone may be used intravenously in 10-unit doses.

The nitrites may produce a lowering of the pulmonary blood pressure and may be of value in this way. It may be used in the form of amyl nitrite or nitroglycerin and should be given in larger doses than normally used.

Purgation in the form of epsom salts lowers the blood pressure and may be used with benefit.

Alum, tannic acid and lead are of no value.

Gelatin best given by mouth may be used but is of doubtful value.

Calcium salts by mouth have long been used but have no influence on the bleeding.

Coagulants such as thromboplastin, coagulin, fibrogen, etc., are all supposed to increase blood coagulation but have been ineffective.

Blood transfusions in small amounts up to 100 cc. of blood have proved of value. Larger amounts increase the blood volume and are therefore of some danger. The question of severe blood loss must of course be considered. Horse serum may be used in nonsensitive cases.

In all cases of pulmonary bleeding it is, of course, essen-

tial to treat the underlying cause, the bleeding often being of minor importance.

SUMMARY

The first consideration in the handling of a case of pulmonary bleeding is a proper diagnosis. The routine use of lipiodol is of tremendous diagnostic value especially in the nontuberculous cases. Bronchoscopy is also a valuable adjunct.

The treatment is primarily the proper management of the underlying lesion. The general methods of treatment are by far the most important. Bed rest, reassurance of the patient, sedation enough to control the cough and allay the patient's mind, all these measures are of prime importance. None of the drugs mentioned above are specific but they may be used in protracted cases. When all the simpler measures have failed, artificial pneumothorax should be used in cases of pulmonary tuberculosis. In undiagnosed cases of continued bleeding, artificial pneumothorax should also be used as a temporary measure.

CLINIC OF DR. J. J. SINGER

FROM THE DEPARTMENT OF MEDICINE, WASHINGTON UNIVERSITY SCHOOL OF MEDICINE AND THE MEDICAL AND SURGICAL CHEST SERVICE OF BARNES HOSPITAL

THE DIAGNOSIS AND PREVENTION OF SILICOSIS (THE SILICOSIS PROBLEM)

Case I.—H. M. was a thirty-one-year-old white man who entered Barnes Hospital March 7, 1932. His complaints were dyspnea, a productive cough, slight fever, night sweats and marked loss of weight. He began to notice symptoms of weakness and shortness of breath about two and one-half years ago after working in a dusty roofing factory, for four years, where gravel with a high silica content was ground for roofing material. Two months later these symptoms became more severe and patient was forced to quit work. After rest he was not improved. A productive cough developed with a thick, dark brown sputum, occasionally blood-streaked.

Physical Examination.—Patient pale, pupils equal, react to light; teeth poor with much caries and pyorrhea. Pharynx congested, no glandular enlargement; chest is emphysematous, diminished breath sounds throughout with fine moist râles heard here and there, no areas of consolidation noted by physical signs; heart sounds are normal; abdomen negative. Laboratory reports are as follows: no acid-fast bacilli found in sputum, guinea-pig injection was negative. Red blood corpuscles, 5,050,000; white blood corpuscles, 13,600; hemoglobin, 83 per cent. Kahn: negative and vital capacity 1370 cc. x-Ray films show a diffuse peribronchial thickening throughout resembling miliary tuberculosis. There was no

evidence of fluid in the chest pleural cavity. Patient treated symptomatically. On April 17, 1932, patient continued to be about the same as a week ago, possibly slightly improved. On April 22, 1932, physical signs and x-ray showed similar condition as before. Areas of pathological compensatory emphysema in close proximity. Fluoroscopy showed no change.

Fig. 34.—Case I. Film taken April 22, 1931. See text for description.

Patient was anxious to go home, although advised not to (discharged April 23, 1932).

Comment.—x-Ray taken on April 22, 1931. At this time patient had symptoms of dyspnea with occasional blood-streaked sputum and weakness. His general appearance was good. This film showed fine nodular thickening throughout both lungs, particularly from hilus to axillary area and to bases of the lung. The air content, however, is generally good; both diaphragms move well and were smooth in outline.

Film taken March 16, 1932. almost one year later. although there was no further exposure to silica dust one notes increase in the amount of density and that the nodular densities have increased both in size and intensity. The right hilus is

Fig. 35.—Case I. Film taken March 16, 1932. See text for description.

thickened, both diaphragms are more irregular and the general air content of the lungs is markedly diminished. With the increase of physical changes noted by x-ray and the stethoscope the symptoms increased accordingly.

Case II.—L. P., age forty-eight years, first admitted to the Barnes Hospital on October 31, 1931. His complaints were dyspnea, cough, pain in the right chest, expectoration, occasionally blood-streaked (never foul) and loss of weight. He was a steel worker between the ages of fifteen and twenty-two years. The next two years were spent in a gold mine,

DISCUSSION

In the past five years the disease known as silicosis has become a very important problem to physicians, lawyers, and industrialists. To each of them the problem is a distinct one, but we as physicians are interested primarily in its cause, prevention and cure.

There have been numerous articles written, particularly in the last five years, regarding silicosis. Much of the work has been undertaken by the United States Government through its Public Health Service and Bureau of Mines. A fair amount of work has been requested by the industrialists.

The first mention of dust disease was by Pliny in 76 A. D.¹ In 1556, Agricola² published an excellent treatise which covered diseases connected with miners. Henry Stuart Willis, in an excellent monograph on the subject entitled, "Pneumoconiosis and Tuberculosis,"³ gives an interesting historical review of the condition known as pneumoconiosis and silicosis from the time of Agricola till the date of the publication of his article in December of 1930. It can be readily seen, therefore, that miners and those in the dusty trades received considerable medical observation and that a certain amount of caution has been expressed to prevent the serious dangers associated with the inhalation of dust.

At the present time health hazards connected with industries in which considerable dust is present are receiving attention from physicians and sanitary engineers interested in the problem. A great improvement in the physical character of industrial plants has resulted so that silicosis, as a disease, may in the future be partly eliminated.

There is still debate among medical men, as to whether symptoms in exposed individuals are actually due to silicosis or to other pulmonary or cardiac diseases. Because of the difference in opinion this question was referred to a committee of the Public Health Association. After analyzing the various symptoms and the diseases with which the patient may be suffering, the committee offered the following definition of silicosis:

"A disease due to breathing air containing silica. characterized anatomically by generalized fibrotic changes and the development of miliary nodulation in both lungs, and clinically by shortness of breath, decreased chest expansion, lessened capacity for work, absence of fever, increased susceptibility to tuberculosis (some or all of which symptoms may be present), and by characteristic x-ray findings."

A diagnosis of silicosis depends on four important factors: (1) etiology; (2) symptomatology; (3) physical signs; and (4) roentgenographic studies. It is necessary in etiology to have the complete history of the patient's occupations at the time of the illness and in the many years preceding. It is well known that considerable exposure to silica may be required to produce an incapacitating condition. Dr. Lanza,⁴ formerly of the Public Health Service, in a discussion of the silicosis problem, states that two years is usually the shortest period of the development of the disease, but usually it is much longer. The dosage of silica has three variables: (1) the amount of dust; (2) the amount of silica content; and (3) the length of time of exposure. These variants are of the utmost importance, as it can be seen that a small amount of dust inhaled for a considerable period of time is just as dangerous as a great deal of dust containing silica in a shorter time. It is possible, by various methods, to count the dust particles in and around the particular workmen, and chemical and physical analysis will show how much of this dust is silica or silicates or other silica contents. Dust particles under 10 microns may be considered hazardous.

One must consider in the history whether a man works where the sand is dry or wet, and whether a particular person wore a mask and whether the mask formed an effective barrier to the inhalation of dust.

The relationship of silicosis and tuberculosis has received attention by numerous authors, particularly by A. E. Russell,⁵ and is discussed fully in Public Health Bulletin No. 187 of the United States Public Health Service. Statistics have

shown definite increase of tuberculosis in those afflicted with silicosis.

Workers who have tuberculosis, even if latent, may develop silicosis more rapidly than those who are not so involved. This is particularly important where there are many negro workers, as they succumb to tuberculosis and silicosis more quickly than the white population. In considering the etiology it must always be remembered that exposure to silica or even the evidence of silicotic deposit in the lungs does not in itself constitute incapacity.

Symptoms.—Symptoms due to silicosis itself are, first, gradual weakness, shortness of breath, which increases slowly but surely with the increase of involvement of the lungs. In the first stage the individual may work quite well and it is only after slight exertion that shortness of breath is noticed. An unproductive cough, frequent colds, and chest pains are usually associated with the early symptoms. But a history of exposure, especially under conditions favorable to silicosis, would lead one to suspect even the faintest thickening of the lung markings in an x-ray film as evidence of the beginning of silicosis. As the disease progresses, the symptoms increase considerably, until shortness of breath is constant more or less all the time. A dry hacking cough appears, and is increased by the slightest exertion. Slight blood-streaked sputum is not unusual. Capacity for work is diminished, loss of strength is noted, but usually work may be continued. As a result of the dyspnea, the symptoms usually associated by some with lack of proper oxygenization manifest themselves, particularly those of slight dizziness, headache, loss of appetite, restlessness, etc.

Hemoptysis appears occasionally, especially in patients who cough. The sputum otherwise is clear and has a bluish tinge, is very viscid and is tenacious. Frank hemoptysis is rare.

In the advanced stage one finds an exaggeration of all these symptoms, shortness of breath being the most important and distressing. Later intestinal symptoms are quite common.

Strange to say, many workers even with advanced disease show little or no loss of weight and may have the appearance of robust individuals. Since occasionally symptoms develop years after exposure, a history of previous employment must be obtained.

Death, when it comes, is rarely due to silicosis itself, but must be attributed to associated tuberculosis, secondary abscess of the lung, bronchiectasis, and cardiac disturbances, tuberculosis being the most important cause of death.

Physical Signs.—The physical signs vary with the amount of involvement. Because of emphysema and a lack of deep breathing, fine changes in sounds are not often obtained until the disease has progressed either to the second or third stage. At this time the signs are often those associated with tuberculosis rather than silicosis. Cavities due to silicosis alone are rarely discovered on physical examination, first, because they are rare, and secondly, because emphysematous lung tissue is usually present around the diseased areas.

Sayers⁶ states, "A certain lack of elasticity of the chest wall" exists during the movement of respiration, together with a somewhat reduced air entry, and a characteristic alteration of the inspiratory murmur from the normal "vesicular" character to a higher pitched to "harshened," "thinned," and commonly somewhat shortened type, the expiratory murmur, although somewhat prolonged, remaining fainter than the inspiratory.

This type of breath with some modification is characteristic of silicosis in all its stages, and has also the significant character of more or less complete generalization. It is first noticeable at the anterior, lateral and basal regions.

Usually there are no accompaniments, but a stray rhonchus may be heard here and there.

Roentgen Examination.—It is the *x*-ray examination which is by far the most important in the diagnosis of silicosis. But here again we have numerous complicating pictures which may be due to other diseases that produce somewhat similar fibrotic changes in the lungs. The *x*-ray interpretation of silicotic chests has been discussed by many writers but definite

statements as to making positive diagnosis are rarely seen. It is quite evident that the shadows on the film may be produced by several pathological conditions and a careful analysis of all the facts of the particular case will help materially in a correct diagnosis.

According to Pancoast and Pendergrass the ability to interpret roentgenograms of cases of pneumoconiosis properly must be based upon several factors which may be enumerated as follows: "A knowledge of the anatomy of the chest and many of the physiological problems associated with its anatomical constituents; thorough familiarity with normal roentgenographic and fluoroscopic appearances; knowledge of the histology of the lungs, and especially of the lymphatic system; clear perception of the pathology of the condition of pneumoconiosis and of all conditions which may simulate it in roentgenographic appearances; experienced intimacy with the roentgenographic appearances of the condition in question and of those that resemble it, based upon fundamental knowledge of the pathology represented; knowledge of the physical factors involved in the production of the suspected or pneumoconiosis; and the employment of the proper technic to show to full advantage any or all of the abnormalities present."

The description of roentgen ray films is divided as follows:

1. Definitely negative.
2. More fibrosis than usual.
3. Decidedly more fibrosis than usual.
4. First-stage silicosis.
5. Second-stage silicosis.
6. Third-stage silicosis.
7. Silicosis plus tuberculosis.

These various classifications are described in great detail in a report by R. R. Sayers-Meriweather-Lanza.⁷ It is quite evident from the classification that the finest changes in the roentgen films must be considered in placing the patient in the proper class. There are striking discrepancies between symptoms and physical signs of pulmonary fibrosis. Often

the symptoms are minimal in spite of great involvement. consequently it has been the custom of those interested in silicosis to consider the diagnosis from a combination of history, physical signs and roentgen ray studies. At times it is so difficult to make a diagnosis that only at autopsy when the lungs are studied chemically and the silica content is found to be above average, can silicosis be positively identified.

The most important x-ray evidence of silicosis is the increase in the bronchial markings, particularly in the bases, with a preference to the right base. As the silica produces an irritation in the lymph channels, which become blocked and thickened due to an inflammatory reaction, the picture will show these structural changes in direct proportion to the amount of involvement, plus secondary complications such as tuberculosis, bronchiectasis and abscess.

McNally⁸ states that: (1) the normal lung contains 1.13 mm. of silicon dioxide per gram of dried tissue. (2) A chemical examination of the lungs should be made in every case coming to autopsy, in which there is a history of a dusty occupation.

Case	Ash per cent	SiO ₂ per Gm. of dried tissue, mg.	Occupation
44	10.78	8.6	Millstone sharpener
503	17.14	14.0	Stone cutter
327	12.36	2.4	Machinist
429	14.58	3.6	Engineering draftsman
463	19.99	4.3	Coal miner, 25 years
411	8.84	5.0	Stone quarryman, 9 years
300	8.46	25.0	Granite cutter
446	5.59	10.9	Zinc miner

It can readily be seen by this table that the greater the exposure to silica the higher content of silica in the dried lung.

Pathology.—Pathological studies on silicotic lungs have been made by Dr. Leroy U. Gardner⁹ of Saranac Lake. A summary of his examination made in 8 postmortems states that the surface of all but one lung presented extensive pleural

adhesions. The sections of the organisms disclosed an appearance which varied with the degree of involvement. The earliest changes due to silicosis alone are small pleural and subpleural nodules of gray fibrous tissue in a lung otherwise not remarkable. The tracheobronchial lymph nodes were small but deeply pigmented and exhibited a few small gray scars. In more advanced cases, sections revealed widespread studding of the tissue with gray-black nodules which were only slightly more compact and firm than the surrounding lung. The distribution was quite general, although the apices and outer third of the lung were somewhat less involved. The remaining parenchyma of the lung exhibited an emphysematous enlargement of the air spaces, readily visible to the naked eye. The tracheobronchial lymph nodes were moderately enlarged and presented a well-defined fibrous body surrounding a dense steel-gray center streaked with lighter bands. The silicotic nodules in cases complicated by tuberculosis were much more dense and much more sharply outlined. They were more steel-gray than black in color and a close examination revealed that they were composed of whorls of silky strands, not unlike the appearance of uterine fibroid tumor. Often they were so closely packed together that a whole lobe seemed to be replaced.

The microscopic appearance in pure silicosis shows slight amounts of dust deposited in the pleural septa and adventitial coats of the vascular and bronchial trunks. These deposits are surrounded by a slight amount of cellular connective tissue. In various alveolae are scattered free phagocytes containing dust particles. As the involvement increases, the evidence of cellular tissue diminishes but is replaced with fibrous tissue, frequently hyaline in character. The blood vessels sometimes are obstructed by endarteritis. The tracheobronchial lymph nodes present even more extensive lesions than are found in the lung. The sinuses are, in most places, obliterated by reaction to excessive amounts of dust or healed and calcified tubercles. Around the node is dense fibrous tissue which had caused a dilatation of the afferent lymph vessels.

Gardner¹⁰ described the silicotic nodules as a "discrete mass of hyaline connective tissue generally surrounded by a capsule of young fibroblasts between which are a great number of dust-filled phagocytes. In the center area the nuclei are compressed to thin elongated spindles lying between very thick, heavy bands of collagen."

Fig. 37.—Barre granite cutter. Two isolated silicotic nodules. Cellular connective tissue borders and hyaline fibrous centers. Thickened interlobular septum extending upward and to the left of the right nodule. Note dilated lymph vessels in septum. (Taken from "A Pathological Study of Eight Lungs from Employees in the Granite Industry," by Dr. Leroy U. Gardner, Pub. Health Bull. 187, Washington, D. C., 1929, p. 138.)

Treatment.—There is no known treatment for silicosis when it is once definitely developed but, at the earliest signs, a change of occupation where the silica hazard does not exist would usually prevent the serious complications. Hemoptysis and dyspnea and pain can be treated symptomatically. The most important contribution to the treatment of silicosis is the prevention.

This has been accomplished by proper safeguards to the

workers by the use of fans, exhaust pumps, filters and inhalators. The change of occupation in plants has been effective.

Compensation to persons afflicted with silicosis has become a legal requirement in most of the states. When compensation is obtained the worker can withdraw from his occupation sooner than otherwise, and thus prevent the later disabling stages of silicosis.

CLINIC OF DR. PARK J. WHITE

WASHINGTON UNIVERSITY SCHOOL OF MEDICINE AND THE
ST. LOUIS CHILDREN'S HOSPITAL

THE CLASSIFICATION AND TREATMENT OF INFANTILE COLIC OR GASTRO-ENTEROSPASM

INFANTILE colic is an excellent example of the difference between "hospital" and "outside" pediatrics. Patients with this condition are not, and should not be, admitted to hospitals.¹ That colic has not lent itself to laboratory study may account in part for the fact that it has escaped the careful classification essential to successful therapy.

Definition.—Assuming that such conditions as hunger, improper feeding, otitis media, etc., have been ruled out, we may take as a working basis the definition of the syndrome of "true colic" given in 1923:² "Vagogenic gastro-enterospasm, the entire alimentary tract being often involved in the (purely functional) hypermotility. The principal manifestations may include (a) extreme fretfulness, usually aggravated by feeding; (b) projectile vomiting; (c) diarrhea or (more rarely) constipation, with or without visible gastric or intestinal peristalsis." Other terms which have been applied to the condition are "hypertonic infant,"³ "vagotonia,"⁴ and "*gastro-névrose émétisante*."⁵

Classification.—The following classification is offered as of practical therapeutic value. The earlier and more accurately one can determine in which of these groups his patient belongs, the earlier he will bring comfort to the sufferer and peace to the parents, to the neighbors, and to himself.

- I. Allergic, or sensitive to: (a) Cow's milk.
(b) Human milk.

(A) *With cutaneous manifestations:*

1. Dermatitis of face or of both face and scalp.
2. Urticaria.

(B) *Without cutaneous manifestations.*

II. Nonallergic.

Colic in Allergic Infants.—In 1921, Shannon presented his observations on colic in breast-fed infants as a result of sensitization to foods in the mother's dietary.⁶ In the following year he published his paper on eczema in breast-fed infants, relating this disorder to the same etiologic factor.⁷ In 1929, I noted that in early infancy, the syndrome of gastroenterospasm associated with eczema is almost three times as common as either condition alone.¹ In that study of 47 infants under three months of age, 27 presented the following sequence of symptoms: colic and diarrhea (simultaneously; less frequently vomiting) at from three to six weeks of age, followed by facial dermatitis at about ten weeks of age. Ten of the 47 had colic alone, and 10 eczema alone. The eczema in those who had it with colic was less severe than in those who had it without colic. Of the 47 patients, 29 were boys and 18 girls—a proportion which holds good for the patients observed since 1929.

In 40 cases studied during the past six years, the incidence of colic without eczema (24 cases, nonallergic) exceeds that of colic with eczema (16 cases, allergic). Accurate figures on the total incidence of both varieties of colic among healthy young infants are of course not available. My impression is that it approximates 1 per cent.

Of the 16 patients with "true allergic colic," 10 were boys, 6 girls.

Illustrative Cases.—1. Jarrett S., a well-developed boy whose severe "cramps" and diarrhea began at the age of two weeks, while on an evaporated milk mixture. There was no family history of allergy. The diarrhea improved on a skimmed milk mixture. At the age of ten weeks he developed

a severe eczematoid dermatitis of the face and scalp. Dryco feeding was instituted with excellent results, the rash clearing almost entirely within two weeks, the fretfulness practically disappearing. At the age of three months he weighed 15 pounds; rice and tapioca (in preference to the more likely allergenic wheat) were added to his diet. Now, at the age of six months, there is only a slight tendency to "scaly scalp." His general condition is excellent.

2. Eloise P., many of whose mother's family suffered severely from various forms of allergy. She was first seen at the age of five months. There was a history of "terrible" colic during the first few weeks of life, followed by extremely "bad" eczema of the face, scalp, and legs. Her colic and eczema did not respond to dryco, nor to sobee, nor to cemac (see below). Evaporated goat's milk with alerdex produced prompt and lasting recovery. At the age of ten months, she was able to tolerate boiled cow's milk. The various cereals had to be given in limited amounts. If these amounts were exceeded, both colic and eczema returned.

At the age of twenty months, she developed eczema in the popliteal folds. This yielded to exclusion of wheat from the diet.

3. Morton N., whose case was exactly similar. He did badly until he was given food free from all animal protein (cemac). He was able to tolerate all cereals except those containing wheat.

4. William C., a well-developed, sturdy boy, whose mother's father and brother were both subject to hay fever. He did very well until the age of eighteen days, when he began to "scream all day," and had 8 stools per twenty-four hours. The breast-milk supply was so small that he was weaned and given a formula of skimmed milk and dextrimaltose. This, together with paregoric and bismuth by mouth, reduced the number of his stools.

Ten days later he developed a facial dermatitis and "yelled with colic." He was given the following formula:

Dryco	28 tablespoonfuls
Harley water	30 ounces
Dextrimaltose	4 tablespoonfuls
6 ounces every four hours, 5 feedings.	

Also elixir phenobarbital, 10 to 15 drops before each feeding. Prompt improvement in both dermatitis and colic resulted. Four weeks later, at the age of nine weeks, he was put on an ordinary evaporated milk mixture without return of his trouble.

An Instance of "Colic" in an Allergic Child of Ten.—This boy, whose paternal grandmother had had asthma, was first seen at the age of ten. He had had colic and facial eczema in early infancy, and had "always had trouble with his stomach; also from 3 to 5 watery stools per day, and had never so long as he or his mother could remember passed a day without frequent abdominal cramps." His mother had for some time suspected him of sensitivity to chocolate.

Examination revealed nothing abnormal. He was 3 pounds under weight. Chocolate and all milk were completely removed from his diet. Within ten days his improvement was striking. His cramps disappeared. He gained weight. Two years later he was able to eat foods cooked with milk; but if he drank even $\frac{1}{2}$ ounce of milk, or if he ate any chocolate or foods flavored with it, his abdominal pains promptly returned.

Only the "proof-of-the-pudding" test was done in this case. Skin tests were not considered necessary.

I present the last case to emphasize that, although it is rarely encountered in later childhood, the syndrome of colic due to allergy may occur then and should be watched for.

Comment on the Treatment of Colic in Allergic Patients.—Obviously, if sensitivity to food is responsible for the colic and eczema of these infants, milk is the food which we must consider. If, as is seldom the case, the mother has an adequate supply of breast milk, the successive elimination of some of the common allergens from her diet is of course advisable. The babies' symptoms begin several weeks before orange juice and cod liver oil are given. It happens that in

only one of the 16 infants observed during the past six years could breast milk be considered a factor. As the mother gave only from 1 to 1½ ounces per feeding, the baby was weaned in order to eliminate as many "unknowns" as possible. In this case an ordinary cow's milk mixture effected some improvement; but half-skimmed milk dried by the Just-Hatmaker roller process (dryco) was eventually required for complete relief. Inasmuch as the other mothers' milk "dried up" before the babies' fretfulness began, what might well be called suckled nervousness could not be held responsible for the subsequent colic.

These babies were all fed on ordinary evaporated milk, sweet milk, or lactic acid milk mixtures before the syndrome of "true colic" made its appearance. And until the eczematoid dermatitis was noted two or three weeks later, the dietary and medicinal treatments of nonallergic gastro-enterospasm were employed (*q. v.*). Once the allergic nature of the colic was established the indication was either to alter the milk so that it could be tolerated, or to give a substitute for milk which would provide all the necessary food constituents. Dryco produced the most consistently good results, presumably because of the alteration of the lactalbumin by the drying process. Ten of the 16 patients were either cured or greatly improved by its use. From two to ten months' feeding of dryco were required before ordinary milk mixtures could be tolerated. The others required either milk-free soy bean flour mixture (sobee) or the vegetable emulsion entirely free from animal protein, known as cemac.

Acidified milk has continued consistently to aggravate infantile colic. I have seen only one enterospastic do well on it, and his improvement lasted for only one month.

All but one of the allergic group were of the "sthenic type" of body build. The one exception was a girl.

Colic in Nonallergic Infants.—Of the 24 patients in this group, 14 were boys and 10 girls. (Thus for both groups, 60 per cent of the patients were boys.) All of these infants were of the "broad or sthenic type" of body build. This accords

with the findings of Haas,² who calls such infants "hyper-tonic."

Ten years ago, atropine was the therapeutic mainstay in the treatment of colic. The fact that in prescribing atropine for infants one must warn the parents of the flushing which is very likely to occur, and of the high fever³ which it less commonly produces, naturally makes one hesitate to use it, and stimulates one's search for reliable dietary means of relief. Hence, in the 24 cases of "nonallergic colic" observed during the past six years, atropine was tried only twice (in severe cases of gastrospasm). In one case there was no benefit, in the other there was a bad reaction.

Illustrative Cases.—1. Ronald H., whose family history was negative for allergy, weighed 5¾ pounds at birth, gained to 16 pounds at four months. When first seen at the age of eight weeks he was on an evaporated milk mixture. He was "very colicky and had a bad diarrhea." He responded very well to the following feeding:

Sweet milk	32 ounces
Farina	5 level tablespoonfuls
Corn syrup	1 tablespoonful
cooked for one and one-half hours in a double boiler to a mushy consistency, divided into 5 equal portions, fed through a Hygeia nipple with the end cut off.	

He became quite constipated, so equivalent amounts of Baby Ralston, later Ralston food were substituted, with resulting normal movements. At the age of ten months he still requires thick cereal.

Case II.—Katherine W., whose family history was negative for allergy, began vomiting (projectile) at the very unusually early age of four days. Atropine was given fifteen minutes before each breast feeding, but it was discontinued after 3 doses because each administration produced cyanosis, without checking the vomiting.

On the fifth day, the following feeding was given:

Pumped breast milk plus sweet milk to make 14 ounces.

Farina 4 tablespoonfuls

Cane sugar 1 tablespoonful

cooked two hours in a double boiler, cooled, divided into 6 "thick feedings," 1 warm feeding every four hours through Hygeia nipple with the end cut off.

The vomiting promptly stopped and the weight curve turned upward. The feedings were of course increased in amount as both appetite and weight increased. Bulgarian milk was given at the age of seven weeks. During the second and third days of this feeding, she began to "shriek," had 10 stools per day, and the projectile vomiting returned. The thick cereal was of course resumed. For ten months, any attempt to change to other food produced the same result. After five months of age, Ralston thick cereal instead of farina was well tolerated, as were also the vegetables purées.

After the age of ten months the "regular second-year diet" produced no untoward effect. Aside from "stomach aches" incidental to teething and to respiratory infections, she has remained free from gastro-intestinal symptoms until the present time (she is now eight years old).

Comment on the Treatment of Nonallergic Patients with Colic.—Additional case reports would be both tedious and profitless. In all cases, whether allergic or nonallergic, until the dietary treatment became effective, elixir of phenobarbital was given before each feeding, in dosage of 10 to 30 drops in a half teaspoonful of water. Its carminative and mildly sedative properties make it very helpful as a temporary measure. When vomiting (gastrospasm) predominates, it is best given fifteen to twenty minutes before each feeding.

Until the "colic" has been fully overcome, the act of feeding often starts the peristaltic rushes with resulting cramps—at times even inability to eat. Feeding "colic" patients oftener than every four hours is inexcusable. A few of these infants are satisfied (even at six to ten weeks of age) with only four feedings in twenty-four hours.

Of the 24 cases in the nonallergic group, 8 were relieved

by the substitution of barley water (usually 4 tablespoonfuls of barley flour boiled one-half hour in a pint of water) for plain water cooked with the sweet milk. Thus it would seem that some cases are "mild" enough to respond to "thin cereal," like barley water with milk; and that others are so severe as to require actual thickening of the food, or at any rate a larger amount of the cereal. In 3 of the 16 patients relieved by the "thick cereal," modification of the milk by barley water was tried first, without success.

In 3 of these 24 cases, time was lost because of the mistaken idea that they belonged in the allergic group. In one case dryco was tried, in another sobee, without improvement. They were promptly relieved by thick farina or thick cream of wheat. It should be borne in mind that some infants who might have gone on to develop such a manifestation of allergy as eczematoid dermatitis may have failed to do so because of alteration of the milk protein (probably lactalbumin) by prolonged cooking with the cereal.

Rationale of Thick Cereal Feeding in Gastrosplasm.—For the past fifteen years, pediatricians have considered thick cereal feeding an important part of the medical, often preoperative, treatment of organic pyloric stenosis. Its beneficial results have been attributed to its consistency, which has been thought to make it mechanically difficult to vomit.

As early as in 1914, the use of thick cereal in the treatment of vomiting was not confined to cases of organic pyloric stenosis. In that year, McClure⁹ reported its successful use in a three and one-half months old infant who was evidently a ruminator. He called the condition "neurotic vomiting," apparently because of the "wilfulness of the vomiting." He did not relate it to the autonomic nervous system. Four years later Sauer¹⁰ published his observations, since more widely known, on 6 cases of neurotic vomiting and 12 cases of organic pyloric stenosis.

The administration of cereal to infants under two months of age would have scandalized teachers and practitioners twenty years ago. Yet my patient, Katherine W., at the age

of four days was unable to retain even breast milk until it was cooked and thickened with farina.¹¹

It would seem that the consistency of the food is not the only factor in its efficacy in either gastrospasm or enterospasm or both. I cannot help taking seriously Rogatz's statement¹² that "a thick cereal promptly becomes thin and liquid in the stomach, because of (1) saliva and (2) body temperature." He found that mashed potato or vegetable purées underwent less liquefaction in the stomach; and that any thick feeding makes the stomach smaller, more circular in shape, and greatly reduces the size of the air bubble.¹³ He considers that this is due to excitation of the peristaltic reflex, with increase in the capacity of the stomach wall to grasp and surround the food.¹⁴ Thus the response of the stomach itself must be considered.

Rationale of Thick Cereal Feeding in Enterospasm.

—When eczematoïd dermatitis, or when careful history alone, indicates the probability of an allergic basis for colic, the mechanism of production of painful peristaltic rushes is not entirely vagogenic, but one of edema and smooth muscle spasm. With regard to treatment, the importance of the point lies in the fact previously noted,¹ that atropine, the vagoplegic, is seldom efficacious in the gastro-enterospasm of allergic infants.

In the nonallergic infants, on the other hand, the mechanism of production of "cramps and rushes" is less clear. Whether the presence of excessive amounts of choline derivatives is a factor is not yet known.¹⁵

The remarkable results of thick cereal feeding in so many of these cases (in which atropine has either failed or has had to be abandoned because of toxic effects) practically constitute a "therapeutic test." The overemphasis which pediatricians have placed on the mechanical effect of the food's consistency has often been misleading. That such a food could help both the vomiting of gastrospasm and the cramps and diarrhea of enterospasm did not occur to me until Dr. T. C. Hempelmann suggested it in consultation on a patient

ten years ago. I had wanted to use it for the infant's projectile vomiting, but feared to do so because of the diarrhea and because the infant was but a month old. The baby's vomiting and diarrhea both responded to thick farina at once.

Effect Similar to That of Barium Emulsion.*—I have long felt that giving an infant (or even an adult) anything as bulky and as nonabsorbable as an emulsion of barium sulphate for roentgenographic purposes would have a soothing effect on excessive and painful contractions of the alimentary tract. Recently I asked Drs. Moore, Larimore, and Zink of our Department of Radiology, also Drs. Ernst and Muench of St. Louis, whether a barium meal could not (temporarily) relieve an infant or adult with intestinal colic. All agreed that they had repeatedly seen such relief occur during and shortly after gastro-intestinal x-ray series. They further agreed that cereal emulsion might well have the same mechanically soothing effect as either barium or bismuth.

If, as has been claimed,^{16, 17} strained vegetables and cellulose given to very young infants can increase the bulk of the stool without increasing peristalsis, neither barium nor thick cereal should prove more stimulating. Of course the roentgenographic dose of barium, or of bismuth, so far exceeds the therapeutic dose that for our purposes these considerations are of only academic interest. Bismuth has been used for years in the treatment of intestinal cramps. In infantile colic

* Since returning proof of this paper, I have read the article, "Infantile Vomiting, Its Relief by x-Ray," by R. A. Higgons, T. West, and M. Duryee, *Jour. Pediatrics*, 9: 81, July, 1936. These authors present records of ten infants with intractable vomiting, one of whom had organic pyloric stenosis. It is their experience that barium alone has no beneficial effect; that relief of vomiting is due to the x-rays (in small dosage). They maintain that x-ray therapy is of value whether the vomiting is due to hypertrophic pyloric stenosis or to "functional pylorospasm." Like Barbour and others, they have noted the beneficial effect of x-rays on the vomiting of pyloric stenosis when the rays have been used in the treatment of thymic enlargement. In my opinion, before definite conclusions can be reached: (1) roentgenologists should be able to "explain the mode of action of the x-rays in these cases; (2) more infants should be given x-ray treatment without preliminary administration of barium meals.

it has never given the consistently good results obtained by thick cereal.

Possible Colloidal-chemical Effect.—Every one of my 16 nonallergic enterospastics receiving thick cereal had previously done badly on a variety of liquid foods. The mothers of 3 of these infants were quite certain that orange juice and water, the only liquid material ingested, regularly produced "upsets." That the mechanical consistency of the food is mainly responsible for its benefit, there can be little doubt. But often the effect of the cereal feeding, and at times even that of adding barley water to the milk, is so striking as to be considered medicinal. We should concede the significance of Gasser's remark,¹⁸ "We have much to learn about the pharmacology and the colloidal chemistry of foodstuffs and their contained gels."

Significance of Body Build, Gastric Secretion and Motility.—Discussing the importance of individual variations in type, Washburn¹⁹ gives a graphic x-ray demonstration of the marked difference in the gastric emptying rates of two normal infants.

Siemens and Ledoux²⁰ performed fractional gastric analyses, balloon motility, and radiologic studies on 12 children of various types of body build. They found no definite relation between gastric secretory function, body build, form and position of the stomach. The motility was found to be somewhat greater in the "broad" type.

Let me repeat that all but one of the 40 patients with both types of colic reported herewith were of the "sthenic," or "broad" type, with every evidence of gastric, oftener intestinal, hypermotility and peristaltic rushes. They were thus quite the opposite of the more relaxed, "asthenic" infants, so likely to acquire visceroptosis with the vertical position.²¹

In our noisy gastro-enterospastics, alimentary hypermotility dominates the picture. Their symptoms are almost uniformly aggravated by acid milks. This observation is substantiated by the fact that Schlutz and Fetter²² found high gastric activity in more than 50 per cent of their cases follow-

ing the ingestion of acidified milks—a much higher motility than was observed with sweet milk, or with evaporated or powdered milks. Such infants may be classified with the 12 cases reported by Sauer, Minsk, and Alexander²³ as having high free acid, rapid emptying time, and good appetite—in complete contrast with the 21 hypo-and-asthenics described by these observers. Feeble premature infants, who *require* acid milks because of their low gastric acidity,^{21, 25} belong more properly to the latter group.

Drugs in the Treatment of Infantile Colic.—Fortunately, the majority of parents, and a rapidly increasing number of physicians, are opposed to the use of drugs in early infancy. Thus, one is likely to be criticized for giving palliative medicines even while waiting for the dietary treatment to take effect.

Atropine.—The methods of administration of this drug have been fully described elsewhere.² It is particularly useful in cases of gastrospasm with projectile vomiting. Owing to the likelihood of atropine fever,⁸ flushing, dilatation of pupils, etc., one is glad to find himself able to avoid this medication. The malic acid compound of belladonna leaves (bellafolin, Sandoz) is less toxic than atropine, which is a racemic derivative.

Phenobarbital.—The relaxing effect of this mild sedative is well-known. When given to infants under three months of age, the elixir should be used, in doses of 10 to 30 drops in $\frac{1}{2}$ teaspoonful of water, immediately or fifteen minutes before each feeding. Presumably it has also a carminative effect. It is an excellent temporary expedient.

Camphorated tincture of opium (paregoric) is justifiable for only a few days (4 to 10 drops in $\frac{1}{2}$ teaspoonful of water before each feeding) when diarrhea is the principal part of the syndrome.

Calcium.—I have never had any reason to suppose that any of my colicky infants was suffering from smooth-muscle tetany. Hence I have not used calcium except occasionally as the caseinate (casec) in bad cases of diarrhea.

Alkalis.—Sodium bicarbonate, sodium citrate ("citrated milk") were formerly used much more than they are today. If acid milks aggravate the various forms of colic, one should of course expect alkali therapy to be beneficial. As a matter of fact, the higher buffer content of sweet cow's milk obviates the necessity of adding alkali; and as far as the starchy cereal is concerned, this is digested by the intestinal juices, which are sufficiently alkaline.

Conclusions.—1. Proper classification of infants with colic or gastro-enterospasm is an important preliminary to proper therapy.

2. Allergic infants, with gastro-enterospasm and eczematoid dermatitis, require alteration of the milk protein by heating or drying, or else some dietetically adequate substitute for milk.

3. Nonallergic infants with gastro-enterospasm can practically always be relieved by thoroughly cooked thick cereal-milk feeding. About one fourth of these cases can be relieved by feeding barley water cooked with the milk.

4. In these functional cases, peristaltic rushes, with intermittent spasmodic contractions of the intestine, make diarrhea commoner than vomiting.

5. Of 16 allergic and 24 nonallergic infants with gastro-enterospasm, all but 1 were of the "sthenic" or "broad" type. Twenty-four were boys.

6. Thick cereal cooked with milk, and even strained vegetables, are very well borne by infants less than three months of age. Peristalsis is not necessarily increased by them, although the stools are larger.

7. The quieting effect of thick cereal is probably due to (a) mechanical action of the bulky, bland food, similar to that of large amounts of bismuth or barium salts, and (b) to colloidal-chemical action of the food gels.

8. Increasing knowledge of both classification and dietary treatment of gastro-enterospasm of early infancy is rendering drugs less important in its therapy. Elixir of phenobarbital is the best temporary expedient.

CLINIC OF DR. EDWARD W. CANNADY

FROM THE DEPARTMENT OF MEDICINE, WASHINGTON UNIVERSITY SCHOOL OF MEDICINE AND THE BARNES HOSPITAL

THE TREATMENT OF UREMIA

THE physician faced with the problem of treating a case of uremia realizes that he is handling a difficult problem with little hope of permanently satisfactory results. The prognosis is grave, and there is seldom hope for ultimate recovery. These patients, however, are often exceedingly uncomfortable, and proper treatment may afford considerable relief in their few remaining days.

Although the term "uremia" includes any disease accompanied by nitrogen retention, the most common etiological factor is kidney insufficiency, and this discussion will be confined to the treatment of uremia due to chronic nephritis, whether it be vascular or renal in origin.

The treatment of uremia should include dietetic, diuretic, as well as symptomatic or supportive measures. It must be remembered that the patient should be treated as a whole and attention not confined to the azotemia while other needs are neglected.

The diet must be nutritious and palatable. Dietary principles should be followed but too rigid restriction of certain constituents may make a diet so distasteful that the patient refuses to consume enough food to meet his basal requirements. Since the uremic patient is seldom very active, a daily intake of 2500 calories is usually sufficient. The greater portion should be derived from the more easily digestible car-

bohydrates such as fruit, fruit juices, vegetables, cereal gruels, sugared desserts, toasted bread, jams and preserves. Carbohydrates should predominate since many uremic patients have difficulty in the digestion of fats and since nausea may be increased by a high fat diet.

Although in chronic cases the protein intake should be moderately restricted, too rigid limitation tends to increase the anemia and cardiac weakness. Formerly, diets containing 25 Gm. or less of protein were often advised. When, however, the protein is so rigidly restricted over a long period, nitrogen equilibrium is not maintained and body protein is consumed. In an acute exacerbation of chronic uremia or in uremia complicating acute nephritis, a protein intake of less than 40 Gm. may be advisable for a few days only. After this interval the protein in an adult's diet should be gradually increased to a daily intake of 50 or 60 Gm.

Frequent determinations of the blood urea or nonprotein nitrogen are often of considerable assistance in determining the optimum level for protein intake and it may be found that a diet containing 60 Gm. a day will have no greater tendency to increase nitrogen retention than would one containing 25 Gm. Ordinarily it is wise to reduce the protein content of the food when nitrogen is rapidly accumulating in the blood.

Protein may take the form of milk, egg, meat and fish. The statement that the "red" meats are harmful and should be avoided has never been established. A small portion of broiled steak is often more palatable and does not produce any more tendency to nitrogen retention than would an equal amount of fish or chicken breast.

It is important to give the patient's family specific instructions regarding the diet. The mere statement that certain foods should be forced and others restricted is not sufficient. O'Hare¹ has devised a practical chart which enables the patient or his family to determine his food allowance within a short time. O'Hare informs the patient that he may have a certain number of points daily. Each point on the chart represents 4 Gm. of protein. There is also included

a list of unrestricted foods high in carbohydrate of which the patient is urged to partake freely.

The writer has found the following diet, which was originated by the dietary service of the Peter Bent Brigham Hospital, useful in cases of chronic uremia. It contains approximately 60 Gm. of protein and sufficient calories for the average patient. The nutrition is usually maintained and often there is no increase in nitrogen retention for a considerable period. The diet is simple, the constituents are interchangeable and easily prepared.

<i>Food</i>	<i>Gm.</i>	<i>Household Measure</i>
<i>Food Morning</i>		
Grapefruit or orange	100	$\frac{1}{2}$
Oatmeal	60	2 tablespoonfuls
Egg		1
Toast	30	1 slice
Butter	5	1 square
Cream (40 per cent)	80	$\frac{1}{2}$ cup
Milk	240	1 cup
Jam	30	2 tablespoonfuls
<i>Food Noon</i>		
Roast mutton, steak or chicken	60	1 small serving (2 ounces)
Baked potato	90	1 medium
Peas with	50	2 tablespoonfuls
Butter or	5	1 square
Onions with	150	1 saucer
Butter	5	1 square
Bread	30	1 slice
Butter	5	1 square
Bavarian cream		1
Fudge	35	2 squares
<i>Food Night</i>		
Lettuce or		2 leaves
Tomatoes, fresh	120	1 tomato
Celery hearts	35	1 serving
String beans with	150	1 saucer
Butter or	5	1 square
Asparagus with	150	1 saucer
Butter	5	1 square
Bread	30	1 slice
Butter	5	1 square
Pears	100	2

The total daily intake of sodium chloride must depend upon the condition of the patient. In the presence of edema and a normal blood chloride salt should be restricted. Many believe that it should be limited to 2 Gm. or less per day. Fishberg² advocates a restriction because of diminution of the ability of the kidneys to excrete salt. In those cases of vomiting followed by hypochloremia, however, he believes that the dietary salt should be increased. Even in the absence of vomiting the blood chloride may in the late stages be low and some patients seem to improve with a salt intake increased to as much as 10 Gm. Because of nausea it may be necessary to administer this by subcutaneous or intravenous routes.

An attempt should be made to increase the amount of urine. The uremic patient excretes urine of a low and fixed specific gravity. Large amounts are required to remove the excretory products normally present in a much smaller urinary volume. Often every attempt to increase the output is met with failure, which in certain cases may depend upon the extent of destruction of the secretory apparatus of the kidney.

Diuretics are seldom of value and must be used cautiously. The most powerful, salyrgan, novasural, mercupurin, may be retained and produce severe mercurial intoxication. The writer has seen diuresis and temporary improvement in a few cases in which salyrgan had been used in conjunction with intravenous fluids. Theobromine and theophylline derivatives may be used but seldom increase the urinary output.

Probably the most effective diuretic in uremia is glucose given intravenously. This is usually administered as a 10 per cent solution and may be given in saline or distilled water. As early as 1894 Beverly Robinson³ advised the use of sodium chloride rectally. Keith⁴ warns that the daily injection of sodium chloride intravenously may cause oliguria. He reported two cases of oliguria following intravenous administration of 10 per cent glucose in 1 per cent saline. Diuresis occurred when the glucose was given without the sodium chloride. Bannick⁵ advised the use of glucose in saline and

suggests 1000 cc. to be given over a forty-five-minute period. He observed no increase in oliguria. Others believe that hypertonic solutions of glucose (20 to 50 per cent) are more effective in producing diuresis but this has not been the experience of the writer.

In the absence of vomiting, adequate amounts of fluid should be administered orally. This may be in the form of water or fruit juices. Often the carbohydrate intake may be increased by adding lactose to fruit juice with the double purpose of increasing carbohydrate and fluid consumption.

In forcing fluids one must always remember that the patient may have a weakened myocardium. Many uremics have had for years hypertension with resultant cardiac damage. The fact that the kidneys are decompensated should not allow one to forget that the cardiovascular system is probably functioning far below its normal efficiency and it is possible that some cases of pulmonary edema have resulted from the injudicious forcing of fluids. It is seldom advisable to exceed a daily fluid intake of 3000 cc. in the uremic patient.

Often bed rest and digitalization will increase the urinary output by improving cardiac efficiency. There is no evidence to show that the tolerance for digitalis differs in the uremic patient. Vomiting may make it difficult to administer orally and intravenous or intramuscular routes may be necessary. Thevetin may be given intravenously in an attempt to improve and maintain cardiac efficiency. The writer recently observed an increase in the urinary output in a case of uremia following thevetin administration in which digitalis had apparently failed. Fantus⁶ advised the administration of strophanthin in these cases. The use of digitalis in uremia could hardly be considered as an emergency measure and need not be given too rapidly. Miraculous improvement could not be expected in the patient in deep coma. Six cat units daily may be administered until evidence of digitalization appears. This should be followed with a maintenance dose of 1 to 2 cat units daily.

Frequently attempts are made to increase extrarenal ex-

cretion. The bowels should be kept open and moderately loose. Profuse diarrhea should be avoided because of its weakening effect upon the patient. The constipated individual may be given magnesium or sodium sulphate in moderate doses. A large dosage of the saline cathartics usually does not produce diarrhea in a uremic patient, while the same dose might cause a marked upset in the normal individual. Recent work⁷ indicates that some caution should be used in the administration of magnesium salts in renal insufficiency. A condition simulating uremia may appear as a result of excessive magnesium administration. One seldom encounters difficulty, however, and frequently sees some improvement when 16 to 30 Gm. of magnesium sulphate are given daily to the uremic patient.

Although sweating is a procedure that has long been popular in the treatment, the amount of nitrogenous material removed by perspiration is insignificant. The procedure is often weakening and its too enthusiastic use has been responsible for collapse. If this measure is to be used it should be done cautiously. Moderately warm baths of thirty minutes' duration followed by wrapping in warm blankets may create a sense of well-being and avoid the collapse following the more drastic procedures.

The patient having convulsive seizures must be handled carefully but treatment should not be delayed. There remains some difference of opinion regarding the etiological factors producing the convulsions. Some contend that cerebral edema produces the episodes while others believe that cerebral anemia is the most frequent cause. In younger individuals cerebral edema is more frequently found. This should be combated by hypertonic fluids. In the face of impending convulsions 50 per cent magnesium sulphate (90 to 180 cc.) may be administered rectally with every attempt made to avoid immediate expulsion. With coma fluids should be given intravenously.

Pollitzer⁸ advised the use of 10 cc. of 10 per cent magnesium sulphate twice daily in children and believes that the

mental condition is improved as a result. Aldrich⁹ uses 100 to 200 cc. of 2 per cent solution intravenously. Fishberg² suggests the administration of 15 cc. of 20 per cent magnesium sulphate intramuscularly in adults. Hypertonic glucose may be given in amounts of 25 to 50 cc. of 50 per cent solution or 100 to 200 cc. of 20 per cent solution.

Venesection often stops convulsions and may control stupor and coma. Approximately 200 to 300 cc. should be removed quickly. In the presence of severe anemia it is wise to follow the phlebotomy with a transfusion of 300 to 400 cc. Bannick⁵ has found that transfusions lessen the anemia and decrease the tendency to epistaxis, which is often a troublesome symptom.

Sedation may be necessary to combat restlessness, headache, and insomnia. The use of opiates should be avoided until other measures have failed. Chloral hydrate or paraldehyde occasionally afford some rest. Sodium phenobarbital subcutaneously has been administered successfully in some cases. It should always be remembered that renal excretion is poor and drug intoxication may occur. Lumbar puncture has relieved the headache and restlessness and reduced the tendency to convulsions in some patients.

After other measures have failed to combat restlessness and delirium it may be necessary to resort to morphine. This should be used cautiously, however, and the respirations should be carefully observed. Small doses are indicated. The writer recently observed one uremic patient develop very alarming Cheyne-Stokes respiration after 0.01 Gm. of morphine. The patient improved after carbon dioxide inhalations and caffeine intravenously. A similar episode occurred several days later when morphine was again administered for severe restlessness. This patient lived several weeks after these two episodes and exhibited Cheyne-Stokes respiration at no other time. Fantus⁶ advises the use of morphine to combat hiccup, dyspnea, cramps, and restlessness.

Pruritus is often very annoying and is usually extremely difficult to control. Fishberg² advises the intravenous injec-

tion of sodium bromide but states that an eruption may occur. O'Hare¹⁰ believes that nothing is as effective as sponging with vinegar or weak acetic acid. Lichtman¹¹ and others have used ergotamine tartrate with success. The writer has recently observed a uremic patient who had considerable relief from pruritus after administration of 1 mg. of ergotamine every night. The possible danger¹² of this drug to the vascular system in a patient with poor renal function must be considered.

Vomiting is often difficult to control. Gastric lavage with 10 per cent sodium bicarbonate solution followed by duodenal tube administration of 1 to 2 liters of warm water or normal saline may prove helpful in some cases. Fishberg² has had some success with cocaine in doses of 0.013 Gm. by mouth. The nauseated patient occasionally is afforded relief by small amounts of ginger ale or carbonated water.

SUMMARY

In treating a patient in uremia, the physician must remember that the prognosis is grave with practically no hope for ultimate recovery. All measures are palliative and therapeutic attempts should be directed toward maintaining the patient's nutrition and keeping him as comfortable and cheerful as possible. The therapy advised above consisting of dietetic, diuretic and supportive measures has been directed toward those purposes. Every patient must be regarded as an individual problem and treated as such. Any safe procedure relieving the distressing symptoms and providing comfort and peace to the uremic patient deserves consideration and commendation.

CLINIC OF DR. DREW LUTEN

FROM THE DEPARTMENT OF INTERNAL MEDICINE, WASHINGTON UNIVERSITY SCHOOL OF MEDICINE AND THE BARNES HOSPITAL

THE SIGNIFICANCE OF ABNORMAL CARDIAC RHYTHMS

DURING recent years clinical conceptions of the significance of abnormal cardiac rhythms have undergone great changes in many particulars. The development of graphic methods of registration of the heart beat twenty-five or thirty years ago led to better understanding of the various abnormalities of rhythm, and thus facilitated clinical differentiation. New interest in the arrhythmias tended to focus attention on them, and to assign them a clinical significance now regarded as being out of proportion to their true importance. Certain abnormal rhythms were regarded as entailing particularly harmful consequences upon the heart muscle, and as being themselves the cause of any attendant cardiac embarrassment. For many years the chief interest of physicians in such cases generally lay in the employment of measures designed primarily to influence the disordered beating, with the object of restoring the myocardium to more normal status by such means. Consideration of factors concerned in the production of the various arrhythmias was secondary to the matter of the treatment of them.

Information regarding certain causes began to accumulate, however, and it was soon recognized that in some instances neither the circumstance of origin nor the consequences of abnormal beating were such as to necessitate special treatment.

In certain cases treatment began to be directed primarily to the abnormal situation producing the arrhythmia rather than to the disordered beating itself.

In more recent years this interest in the origin of the arrhythmias has increased. Consideration is given to the matter of cause as well as to question of effects. At present there is a growing tendency to consider abnormal beating of the heart in connection with other abnormalities observed in the patient; to view it in relation not to the heart alone, but to the various factors concerned in the heart beat. Attention is given not only to the heart muscle but to toxic and nervous influences, direct and indirect, which are known to influence the initiation and propagation of contraction. Extracardiac factors are considered.

Whatever ultimate factors may be concerned in abnormal beating, however, it is obvious that the immediate causes in a particular case must be referred to that part of the heart in which the arrhythmia arises. It is not within the province of this discussion to attempt any analysis of the precise physiologic processes of nerve and muscle responsible for the origin and propagation of impulses in the heart. Many aspects of this complex problem are unsolved. It is well known, however, that both muscle and nerve factors are concerned, and that in proportionate importance both are subject to great variation. In certain instances either the nervous or the muscle elements may predominate; upon occasion one or the other may be negligible. The nervous factor, moreover, may be applied ultimately through reflex channels, no cardiac lesion being involved.

In assessing the significance of an abnormal cardiac rhythm in any case, it thus becomes apparent that interest attaches not only to the question of the integrity of the heart but to possible extracardiac influences as well. Either may be the sole causative factor, both may be involved. Abnormal beating of the heart thus may be a diagnostic sign of great importance. Its presence may indicate disease in the heart demanding treatment, or disorder in some other part of the

body calling for primary attention. In both classes of cases, however, consideration must be given also to the following questions: (a) does the arrhythmia *per se* interfere with the functional efficiency of the heart, and if so, to what extent? (b) If functional efficiency is impaired, what therapeutic measures, if any, may be employed directly to obviate the harmful effects of the abnormal rhythm, in addition to appropriate measures directed toward combating the disorder causing the arrhythmia? In other words, does the arrhythmia itself require special treatment irrespective of the condition which produces it?

In the cases of some abnormal rhythms, cardiac efficiency may suffer great temporary embarrassment even though little permanent damage accrue to the heart. The general circulation is impaired. In other instances, neither cardiac nor general circulatory effects are in evidence. Certain disordered rhythms frequently arise as a result of some condition which itself is associated with cardiac insufficiency, and it is largely due to this circumstance that the harmful effects of arrhythmias in general have been exaggerated. More commonly in such cases the abnormal condition producing the arrhythmia is responsible for a much greater degree of cardiac embarrassment than the abnormal rhythm itself produces. While in some instances, therefore, therapeutic measures may appropriately be directed toward combating the ill effects of abnormal beating, it is much more frequently the case that the arrhythmia *per se* demands no special treatment, therapy being directed simply to the underlying disease. In most cases the treatment of a patient with an abnormal rhythm is identical with the treatment that patient should receive were his heart beating normally. As with fever, chills, leukocytosis, and other manifestations of abnormal situations, cardiac irregularity may be the sign which points the way to correct diagnosis, and consequently to appropriate therapy; but it is not to the sign that therapeutic measures are directed. As with other signs and symptoms, there are certain exceptions to the general rule that irregular heart action calls for no special

In certain cases treatment began to be directed primarily to the abnormal situation producing the arrhythmia rather than to the disordered beating itself.

In more recent years this interest in the origin of the arrhythmias has increased. Consideration is given to the matter of cause as well as to question of effects. At present there is a growing tendency to consider abnormal beating of the heart in connection with other abnormalities observed in the patient; to view it in relation not to the heart alone, but to the various factors concerned in the heart beat. Attention is given not only to the heart muscle but to toxic and nervous influences, direct and indirect, which are known to influence the initiation and propagation of contraction. Extra-cardiac factors are considered.

Whatever ultimate factors may be concerned in abnormal beating, however, it is obvious that the immediate causes in a particular case must be referred to that part of the heart in which the arrhythmia arises. It is not within the province of this discussion to attempt any analysis of the precise physiologic processes of nerve and muscle responsible for the origin and propagation of impulses in the heart. Many aspects of this complex problem are unsolved. It is well known, however, that both muscle and nerve factors are concerned, and that in proportionate importance both are subject to great variation. In certain instances either the nervous or the muscle elements may predominate; upon occasion one or the other may be negligible. The nervous factor, moreover, may be applied ultimately through reflex channels, no cardiac lesion being involved.

In assessing the significance of an abnormal cardiac rhythm in any case, it thus becomes apparent that interest attaches not only to the question of the integrity of the heart but to possible extracardiac influences as well. Either may be the sole causative factor, both may be involved. Abnormal beating of the heart thus may be a diagnostic sign of great importance. Its presence may indicate disease in the heart demanding treatment, or disorder in some other part of the

body calling for primary attention. In both classes of cases, however, consideration must be given also to the following questions: (a) does the arrhythmia *per se* interfere with the functional efficiency of the heart, and if so, to what extent? (b) If functional efficiency is impaired, what therapeutic measures, if any, may be employed directly to obviate the harmful effects of the abnormal rhythm, in addition to appropriate measures directed toward combating the disorder causing the arrhythmia? In other words, does the arrhythmia itself require special treatment irrespective of the condition which produces it?

In the cases of some abnormal rhythms, cardiac efficiency may suffer great temporary embarrassment even though little permanent damage accrue to the heart. The general circulation is impaired. In other instances, neither cardiac nor general circulatory effects are in evidence. Certain disordered rhythms frequently arise as a result of some condition which itself is associated with cardiac insufficiency, and it is largely due to this circumstance that the harmful effects of arrhythmias in general have been exaggerated. More commonly in such cases the abnormal condition producing the arrhythmia is responsible for a much greater degree of cardiac embarrassment than the abnormal rhythm itself produces. While in some instances, therefore, therapeutic measures may appropriately be directed toward combating the ill effects of abnormal beating, it is much more frequently the case that the arrhythmia *per se* demands no special treatment, therapy being directed simply to the underlying disease. In most cases the treatment of a patient with an abnormal rhythm is identical with the treatment that patient should receive were his heart beating normally. As with fever, chills, leukocytosis, and other manifestations of abnormal situations, cardiac irregularity may be the sign which points the way to correct diagnosis, and consequently to appropriate therapy; but it is not to the sign that therapeutic measures are directed. As with other signs and symptoms, there are certain exceptions to the general rule that irregular heart action calls for no special

treatment. They will be noted in the following brief consideration of the several abnormal rhythms.

Sinus Arrhythmia.—The mechanism for reflex change in heart rate is delicately adjusted so as to respond readily to various influences. Demonstrable variation in sinus rate is common in healthy subjects at rest, representing an exaggeration of normal physiologic processes. Sinus arrhythmia of nervous origin frequently occurs in response to causes which have little effect upon the heart other than the variation in rate, the vast majority of instances falling into this category. Pathologic processes of the auricle also may be responsible, minor as well as serious lesions. It is not unusual for high-grade sinus arrhythmia to be noted in certain cases of coronary thrombosis. That it may result from the administration of digitalis is well recognized.

This irregularity, the simplest as well as the commonest of the arrhythmias, exemplifies the general principles stated above; viz., that irregular heart action is a sign which calls for examination, that it may result from causes of various degrees of seriousness, and that in general it requires for itself no special therapy, treatment of the patient being directed to the condition which produces it.

Extrasystoles.—While it is true that the organized tissues of the heart under certain circumstances are able to initiate spontaneous contractions under the usual normal conditions of activity when exercised. In the strictest sense, they should be regarded as pathologic, but they are usually separate the nervous and muscular elaboration of spontaneous beats. The particular situation responsible is usually intracardiac or extracardiac. Wherever it appears in many instances to represent an exaggeration of physiologic processes rather than a true pathologic condition in the usual sense. Premature contractions may be produced experimentally through electrical stimulation,⁹ and many instances of clinical

pear to rest upon this basis. Other reflex pathways also may be involved, extrasystoles of emotional origin⁴ being well recognized.

On the other hand, the ultimate cause may lay in the heart muscle, where it may represent a negligible lesion or one of extremely serious import. In the cases of patients predisposed to extrasystoles, slight change in the status of muscle or nerves may be sufficient to evoke them. A deep breath may suffice. Toxemia, mild or severe, fatigue, loss of sleep, or any situation which lowers the general level of bodily well-being may produce these interruptions to regular heart action. While it is impossible in any case to determine the precise degree of nerve or of muscle influence in the occurrence of an extrasystole, it is quite frequently possible to refer them chiefly to nervous or to myocardial origin. In general, premature contractions arising in the auricle are more likely to result from nervous influences, those of ventricular origin to be due to muscular factors.

Extrasystoles call not only for examination of the heart, but for complete examination of the patient. In many cases, no cause is found. Therapy appropriate to the etiologic factor, if discovered, should be instituted, but usually the arrhythmia itself demands no treatment. In some cases, however, the patient is so annoyed or perturbed by the irregularity that special measures should be employed to mitigate it. Strychnine frequently is effective. The more rapidly eliminated barbiturates may be useful. On the other hand, there is experimental evidence that barbiturates may cause extrasystoles. Digitalis is a frequent cause, while upon occasion the drug may abolish the arrhythmia.

Auricular Fibrillation; Auricular Flutter.—These arrhythmias are so nearly related that they will be considered together. In origin they are closely akin to auricular extrasystoles. In general what has just been said with regard to auricular premature beats applies also to auricular fibrillation and flutter. Although most cases occur in patients with heart disease, it is now recognized that these arrhythmias may occur

in the auricle of a heart which gives no evidence of any abnormality of the ventricular muscle, and no sign of impaired function.^{1, 2, 5, 8} They are auricular phenomena, and it is to the auricle that their etiology must immediately be referred. This discussion will be confined particularly to fibrillation, but in substance it is equally applicable to flutter.

The general principles which link auricular fibrillation (and flutter) with auricular extrasystoles in etiology and in clinical significance, are subject to certain special considerations. As with extrasystoles, the proportionate influence of nervous and (auricular) muscle factors is subject to great variation, auricular fibrillation of purely nervous origin being well recognized.^{1, 2} The probability of definite auricular lesion, however, is much greater in fibrillation than in extrasystoles. The proportion of cases with (ventricular) myocardial disease also is conspicuously larger. This special association of fibrillation with clinical heart disease rests upon the following explanation. While nervous factors alone may suffice, in general the initiation of fibrillation requires greater insult to the auricular wall, or at all events is greatly facilitated by it. Auricular lesions obviously are much commoner in the cases of patients with more extensive heart disease. Such lesions as mural thrombi, scarring, and fibrosis are noted in many reports of cases which come to autopsy in which examination has been directed to the auricle. The changes attendant on older age⁶ appear to be important factors, auricular fibrillation occurring particularly in older patients. It is relatively infrequent in the heart disease of children, although in such cases another factor which appears to be of great importance in precipitating the arrhythmia commonly is present, *i. e.*, stretching of the auricular wall.^{5, 7} The vast majority of instances of established auricular fibrillation are observed in older subjects in cases of congestive heart failure, and in cases of mitral disease with or without congestive failure. In both situations the increase in intra-auricular pressure tends to induce stretching of the auricular musculature. That increase in pressure within the auricle as an

important element in the disorder is indicated also upon experimental evidence.

The etiology of auricular fibrillation may briefly be summarized: it may arise from nervous or muscular factors in varying relationship. The commonest precipitating cause is the increased pressure of congestive heart failure applied to the wall of an auricle in which certain pathologic processes have occurred.

Quinidine abolishes the abnormal rhythm in many instances. If the basic causes are persistent and of great force, however, the arrhythmia usually does not yield permanently to quinidine. Particularly in cases unassociated with serious heart disease or with congestive failure, the drug may restore normal cardiac rhythm and thus free the patient of the annoyance and of any other ill effects of the disorder.

Auricular fibrillation may occur as an incident in the course of many abnormal situations.^{3, 10} Quinidine or other measures to abolish it may properly be employed in occasional cases in which the arrhythmia itself is of more consequence than a relatively unimportant cause, or in cases in which the cause is obscure. In any case, however, it calls first for examination. Search should be made for other evidences of congestive heart failure, of which fibrillation is frequently a sign.⁷ Thyroid disease and other toxic factors must be considered. Nervous influences are to be kept in mind. The arrhythmia may be an important sign leading to correct diagnosis, and to appropriate therapy. In most instances some degree of heart failure is observed, and in such cases obviously digitalis is to be employed. In cases of other etiology it is equally obvious that other therapy is indicated. It is as erroneous to administer digitalis in cases of auricular fibrillation unassociated with heart failure as it is to omit the drug in instances in which heart failure is the cause. Digitalis does not slow the ventricular rate in nonheart-failure cases,^{5, 6} and in such cases of toxic etiology the drug may be disadvantageous. Auricular fibrillation is no more a general indication

for digitalis than is dyspnea or edema. It is to the underlying situation that treatment regularly must be directed.

Auriculoventricular Block.—Although in occasional instances vagus influence is known to be responsible, the various grades of auriculoventricular block in most cases result wholly or in most part from lesions of some portion of the ventricular muscle. Heart block generally is a sign of myocardial disease. Upon occasion a lesion apparently confined to the auriculoventricular bundle is responsible, but usually disease processes are not so closely restricted, grave myocardial involvement being inferred in most cases.

Adjustment in blood pressure usually compensates for the slow rate of complete block, the ultimate prognosis being determined largely by the character and extent of the myocardial involvement. Therapy is to be directed to the basic disease in question. Special treatment of the block usually is not indicated, but in cases with Adams-Stokes attacks measures designed specifically to prevent recurrence should be tried.

Paroxysmal Tachycardia.—Auricular fibrillation and flutter not infrequently occur in paroxysms, the etiologic agents being either of limited duration or of lesser degrees of potency. Such paroxysmal attacks thus may constitute particularly valuable signs in early diagnosis. As a rule quinidine is employed more appropriately in such cases than in established fibrillation.

Other paroxysmal tachycardias are to be differentiated. Those of supraventricular origin commonly occur in the cases of patients without important heart disease, due chiefly to toxic or nervous influences. Change of position is a frequent precipitating cause. Usually they carry no very great implication of serious import, yielding to milder sedatives and to the reassurance which may truthfully be given. Such a simple procedure as pressure over the carotid sinus may suffice to end the paroxysm.

Ventricular tachycardia, on the other hand, generally occurs only in the presence of serious myocardial insult. It is a sign, therefore, of considerable gravity. It is not uncommon

for an independent ventricular rhythm to result from serious digitalis intoxication or from myocardial infarction. The abnormal sequence of contraction of the ventricular muscle parts renders systole less effective in expelling blood. Serious impairment of the circulation may result and render it advisable to employ measures designed primarily to abolish the abnormal rhythm. In most instances the attack subsides spontaneously before occasion for specific treatment arises. In the average case, therefore, there may be less danger³ in the employment only of general measures than in precipitate special therapy.

Alternation.—Except for brief occurrence, variation in the force of alternate ventricular contractions occurs only in the presence of grave myocardial embarrassment. Continual alternation is of serious import. It is not a disease entity, but an evidence of serious impairment of myocardial function. Its correction rests only upon measures that restore the myocardium to more normal status.

It will be observed that alternation, perhaps the gravest of continued arrhythmias, in common with sinus arrhythmia, the simplest of them, illustrates the principles generally applicable to all; it is a sign, not a disease. Consideration must be given to the cause, rather than to the sign; treatment must be directed to the heart, rather than to the heart beat.

CLINIC OF DR. ARTHUR E. STRAUSS

CARDIOVASCULAR DIVISION, WASHINGTON UNIVERSITY CLINICS

TREATMENT OF MYOCARDIAL INSUFFICIENCY

THE treatment of myocardial insufficiency, like that of any other condition, depends upon the accuracy of the diagnosis and a proper interpretation of the significance of that diagnosis together with an analysis of the indications for treatment and of the methods available. It is not our intention to discuss the diagnosis of myocardial insufficiency but mention must be made of the fact that myocardial insufficiency may be of several grades, the treatment of which will naturally differ if not in kind, at least in degree. In discussing this phase it will be well to use the Functional Classification of Heart Disease of the American Heart Association. This classification divides patients with organic heart disease into three groups as follows:

Class I—Patients with organic disease, but able to carry on ordinary physical activity.

Class II—Patients with organic disease, but unable to carry on ordinary physical activity (without discomfort).

(A) Activity slightly limited.

(B) Activity greatly limited.

Class III—Patients with organic disease, but unable to carry on any physical activity, *i. e.*, who must remain in bed or in a chair.

Patients in Class I are included in this consideration of treatment of myocardial insufficiency, though there may be

some who object to their inclusion, because we believe that it is this group that should be considered as having *potential* myocardial insufficiency and thus a proper group for prophylactic treatment. Digitalis and other cardiac drugs usually are not indicated at this stage of the disease, though advocated by some as a prophylactic measure. It is this group of patients who should be taught the value of moderation, the proper relationship of activity and rest (not invalidism), the importance of avoidance of infections, etc. It is also with this group that so much can be accomplished by proper appreciation and treatment of the etiological agent, especially if it be active, such as syphilis or thyrotoxicosis. Let us pause here long enough to emphasize that no treatment of myocardial insufficiency is adequate unless consideration is given to the etiology. Some of the recent advances in cardiology are due to the emphasis placed upon the proper and complete classification of heart disease which has led not only to better diagnosis and understanding of the problems but in turn has resulted in better treatment. Our task would be poorly done if we treated a case of thyroid heart disease with decompensation with rest and digitalis (or quinidine) and neglected care of the abnormal thyroid state underlying it.

We would be overlooking an important element if we failed to recognize an adherent mediastinopericarditis as the factor in certain cases of decompensation and did not consider surgery as an adjunct treatment. Similarly when syphilis is the cause of heart disease, we must give due consideration to antiluetic treatment.

We shall not consider the treatment of acute myocardial insufficiency except to mention that here again treatment of the underlying and causative agent is important.

We shall now consider the treatment of patients who belong in Class II and III, those with varying degrees of myocardial insufficiency, from the mild to the severe.

As soon as we think of treatment in heart disease our minds immediately frame the picture of our chief defenses—digitalis and rest. Truly, these have been and remain our

chief weapons but a battle is not always won by using only the staunchest strongholds or the largest guns, so we must frequently fortify the action of digitalis with diuretics and procure rest with sedatives, hypnotics and opiates. Treatment of heart disease, however, is not quite so simple. As in warfare we adapt our attack to the character of the enemy, his number and aggressiveness, the terrain of the battle, and many other factors, so in the treatment of heart disease we must consider the character of the disease, its severity, its activity, the complications and the individual who has the affection.

What are the indications for digitalis and how shall we use it? While we are indebted to William Withering who published his treatise in 1785 for the introduction of digitalis to physicians, we have added greatly to our knowledge of its use in recent years.

There are two chief indications for the exhibition of digitalis: (1) decompensation and (2) auricular fibrillation. Perhaps it will be well to amplify that statement. By decompensation we mean the presence or development of symptoms or signs of congestive heart failure from the earliest stage of increasing dyspnea, cough, basal râles, etc., through the extreme state of orthopnea, general anasarca and the like. As already stated digitalis is not indicated because of the presence of cardiac pathological anatomy alone, but on the contrary it is indicated with decompensation regardless of the pathology present. Also, with the establishment of permanent auricular fibrillation digitalis is indicated, regardless of the state of compensation, in practically all cases for the purpose of slowing the ventricular rate and making all ventricular contractions effective; furthermore, digitalis must be continued in appropriate dosage as long as such fibrillation lasts, that is throughout the patient's life unless the fibrillation spontaneously or by the action of such drugs as quinidine changes to normal mechanism. The exceptional case of the naturally slow ventricular rate in untreated auricular fibrillation, probably due

to inherent conduction defects, not needing digitalis merely proves the rule.

The more we know of the action of digitalis, pharmacologic, physiologic and toxic, the better will we be able to use it. Withering working with the crude unstandardized drug clearly understood many of its actions and enunciated a century and a half ago the principles which we still use today. "Let the medicine be continued until it acts either on the stomach, the kidneys, the pulse, or the bowels; let it be stopped upon the first indication of any of these effects." He thus recognized the toxic nausea, the beneficial diuresis and slowing of the pulse in auricular fibrillation, not then recognized as such, the production of extrasystoles and heart block as toxic manifestations together with the occasional diarrhea.

In recent years we have been fortunate in having many well standardized and relatively stable digitalis products and in learning through careful study the average tolerance of an individual. Eggleston in 1915 showed that it required 15 cc. of an average high-grade standard tincture of digitalis (1.5 Gm. of the dried leaf) per 100 pounds of body weight to completely digitalize an individual. While we must not use this figure as an absolute and unchangeable dosage, it does serve as a guide and much of our modern use of digitalis dates from that work.

For several years we have heard much about the standardization of digitalis by cat units and the United States Pharmacopeia has designated that 1 cat unit is equivalent to 0.1 Gm. of standardized powdered digitalis leaf (1 cc. of the tincture), the cat unit being the weight of the dried drug in milligram necessary to kill 1 Kg. of cat in one and one-half hours. While we need not concern ourselves with cat units, we must, however, be sure we are using a standardized and potent preparation.

Whether we quickly or slowly digitalize a patient will depend upon the exigencies of the occasion, both methods having value. Rapid digitalization is indicated when the patient is in severe decompensation and the time element plays an im-

portant part either because of the severity of the symptoms or the danger to life, though many believe that quick digitalization is desirable in all stages of decompensation. However, it must not be inferred from this statement that digitalis is an emergency drug, for this is but rarely the case though it often has urgent indications. With rapid digitalization we must be certain that none of the drugs of the digitalis series have been used in the preceding three weeks, or if used we must take the amount into consideration in estimating the dosage. For a previously undigitalized individual of 160 pounds, whose estimated requirement would be 2.4 Gm. of the powdered leaf (24 cc. of the tincture) the following schedule would provide relatively rapid and yet safe digitalization:

- 1st Dose, $\frac{1}{4}$ calculated dose, 0.8 Gm. (powdered leaf) (8 cc. tinc.)
- 2nd Dose, 6 hours later, $\frac{1}{6}$ calculated dose, 0.4 Gm. (4 cc. tinc.)
- 3rd Dose, 6 hours later, $\frac{1}{12}$ calculated dose, 0.2 Gm. (2 cc. tinc.)
- 4th Dose, 6 hours later, $\frac{1}{24}$ calculated dose, 0.1 Gm. (1 cc. tinc.)
- 5th Dose, 6 hours later, $\frac{1}{24}$ calculated dose, 0.1 Gm. (1 cc. tinc.)
- Total— $\frac{2}{3}$ calculated dose, 1.6 Gm. (16 cc. tincture) in 24 hours.

The dose of 0.1 Gm. (1 cc. tincture) may be repeated every six hours thereafter until full digitalization has been obtained. For maintenance of full digitalis effect we use approximately 0.15 Gm. of the powdered leaf (1.5 cc. tincture) daily, many using 0.1 Gm. (1 cc. tincture) or 1 cat unit as the daily maintenance dose though this figure is subject to wide variation. The recent trend has been toward the use of the powdered leaf in tablet, pill or capsule form, and in our work in the clinic and hospital as well as in private practice, we have practically discarded the use of the tincture, though it too is very satisfactory if we are sure of its potency and if we always keep in mind the fact that a drop is not a minim of tincture digitalis, there being in fact an average of $2\frac{1}{2}$ to 3 drops to the minim.

Because most of the pharmaceutical preparations are now prepared in 0.1 Gm. (1 cat unit) size, though some are scored for easy division, we have found it convenient when prescribing a maintenance dose of digitalis of 0.15 Gm. daily to

have the patient take a tablet of 0.1 Gm. one day and 2 tablets the next day, alternately, instead of $1\frac{1}{2}$ tablets daily, using an ever handy calendar as the guide, taking 1 tablet on the odd days of the month and 2 on the even days.

When rapid digitalization is not indicated, there will naturally be a wide variation in the method of dosage, depending upon individual factors such as degree of decompensation, ventricular rate in fibrillation, frequency of visits of the ambulatory patient, etc., but a satisfactory method for this small divided dose régime is 0.1 to 0.2 Gm. (1 to 2 cc. tincture) two or three times daily, until digitalis effect or toxic effect is observed, then reducing the daily dose to the maintenance level, 0.15 Gm. (1.5 cc. tincture) daily. Again, I must emphasize the fact that a drop is not a minim. A clear understanding of our aims in digitalizing and of the toxic effects of digitalis is necessary for best results.

Aside from the rare use of strophanthin in doses of 0.5 mg. (not over 1 mg. daily) intravenously in emergency cases, a use not wholly unattended by danger, we need consider but one other member of the digitalis series.

Recently an active cardiac glucoside with digitalis-like action has been isolated from the bestill nut and given the name, thevetin. This active principle has been tested and its potency and toxicity have been shown to be one seventh that of ouabain. It too is standardized in cat units and is obtainable in 2-cc. ampules containing in solution 0.00275 Gm. ($\frac{1}{4}$ grain) of the active drug, equivalent to 3 cat units. We are at present maintaining adequate "digitalization" by giving one such ampule (3 cat units) intravenously every other day. This drug at present can only be given intravenously and whether or not it will maintain a place in our armamentarium remains to be seen.

Ranking with digitalis and equally necessary in the treatment of the cardiac patient is rest, varying all the way from simple limitation of activity to absolute bed rest, the latter so valuable in the severely decompensated case. Care in securing and assuring this rest is very important, and attention

to detail is well rewarded. It is the very exceptional, in fact one might say almost unique, patient who cannot remain in bed, though many attempt to convince the physician that they must sit up in a chair; and herein lies the value of adjunct treatment with sedatives, hypnotics, and opiates. A good rule is to begin the bed treatment (either at home or in the hospital) of the severely decompensated cardiac with a hypodermic injection of morphine (10 to 15 mg., $\frac{1}{6}$ to $\frac{1}{4}$ grain) for the first two or three nights and then substitute a non-narcotic hypnotic. At certain stages in treatment the anxiety state of the patient plays as important a rôle as the myocardial insufficiency and proper sedation is extremely valuable.

While digitalis and rest will usually produce an adequate diuresis, there are some patients whose edema persists despite these measures. For such patients we have a group of diuretic drugs which are very helpful in the continuation treatment of myocardial insufficiency. Usually we do not prescribe these diuretics until the patient has become fully digitalized but occasionally when the edema is of marked degree we may use the diuretics at the outset along with digitalis and rest. There are a large number of diuretics on the market but our experience has led us to rely upon but few of them in producing adequate diuresis. Despite the frequent mention and use of theobromine-sodio-salicylate (diuretin) or theobromine-calcium-salicylate (theocalcin) we have not obtained (except in very rare instances) an effective diuresis with the usually recommended doses 0.5 to 1 Gm. ($7\frac{1}{2}$ to 15 grains) three or four times a day or even with much larger doses of 6 to 8 Gm. (90 to 120 grains) daily.

On the other hand we have often produced a beautiful diuresis with theophyllin (theocin) given in doses of 0.3 Gm. (5 grains) three times a day for two days, omitting two days and repeating. Unfortunately this effective dose usually produces undesirable side actions, nausea, vomiting, headache and increased irritability, so that experience has taught us to prescribe it in smaller dosage 0.2 Gm. (3 grains) in the manner above described. While the diuresis with this dose is usually

not as great, it is still effective in many cases. Even with this dose increased irritability and headache may occur, especially on the second day of administration and we have attempted to overcome this undesirable effect by combining it with a small dose of a sedative, as for instance, phenobarbital 0.015 to 0.03 Gm. ($\frac{1}{4}$ to $\frac{1}{2}$ grain), or amytal 0.03 to 0.045 Gm. ($\frac{1}{2}$ to $\frac{3}{4}$ grain) with each dose. Such combination usually is effective in preventing these side actions.

As effective as has been the diuresis from theophyllin, in just opposite measure has been our experience with its double salt, theophyllin-ethylene-diamine (aminophyllin, metaphyllin, euphyllin) which in doses of 0.09 Gm. ($1\frac{1}{2}$ grains) three times a day, or double this dose has only rarely given us effective diuresis. I do not refer here to the use of this drug as a coronary dilator, but merely as a diuretic.

Lately some claim has been made that aminophyllin properly administered will relieve Cheyne-Stokes respiration in myocardial insufficiency, a claim that if proved will be of great value in our treatment as Cheyne-Stokes breathing is often one of the most distressing of symptoms in cardiac decompensation.

Since the introduction of the mercurial diuretics, we have come to look upon them as the most dependable. The original one, novasurol, has been replaced entirely (because of greater effectiveness and less toxicity) by salyrgan and mercupurin, the latter of more recent introduction, being a mercurial and theophyllin in chemical and free combination. Both of these diuretics are very effective often giving a diuresis of 3000 to 8000 cc. in twenty-four hours, the complete diuresis usually being only of this duration. These diuretics must be given intravenously (preferably) or intramuscularly, never subcutaneously and are given in doses of 1 to 2 cc. at intervals of a few days or longer as needed. An original dose of $\frac{1}{2}$ cc. is usually given to test the patient's susceptibility.

The effectiveness of salyrgan and mercupurin is usually enhanced by the previous ingestion of ammonium chloride (or nitrate) in doses of 4 to 8 Gm. (60 to 120 grains) (enteric-

coated tablets) daily for three to four days before the mercurial injection.

In the hands of some, urea in large doses (15 to 60 Gm. daily) over a long period has been effective as a diuretic but we have found much objection to the taste and have not found it as effective as theocin, salyrgan, and mercupurin. The latter in most cases of myocardial insufficiency has been the most effective diuretic, especially when given after ammonium chloride.

Occasionally a hypertonic glucose solution (50 to 100 cc. of a 50 per cent solution) is effective as a diuretic, especially when there has been a temporary suppression of urine as in the circulatory shock and failure following coronary occlusion, but glucose has not come up to expectation in general experience. Perhaps it has its greatest usefulness in the cardiac failure of diphtheria. When such a hypertonic solution of glucose is given intravenously, great care must be taken to have the solution at body temperature and to inject it very slowly to prevent venous thrombosis.

Speaking of glucose brings up the subject of diet in the treatment of myocardial insufficiency. The high carbohydrate Smith cardiac diet usually has to be modified as most patients will not take the full diet without complaining of its sweetness. Recently emphasis has been placed on a low caloric diet (following the now current vogue of keeping metabolism at a low ebb) in myocardial insufficiency but we have not yet been convinced of its value, except perhaps in the early stage of treatment (not for a prolonged period) and in the obese. The old Karell diet still has its place in the severely decompensated patient with marked edema but this diet must not be continued for more than a few days.

Generally speaking, a diet adapted to the bedridden patient—whose appetite is usually poor—and which is correctly balanced is the proper diet. This means adequate protein for nitrogen balance—50 to 60 Gm. on the average—and ample carbohydrates with attention in the long drawn-out cases to the necessary vitamin, caloric and mineral (iron especially)

content. The food should be easily digestible, and in the case of very sick patients, should not require much chewing. Limitation of fluids to 1200 to 1500 cc. in twenty-four hours is usually desirable when edema is present, but due consideration must be given to the patient's comfort, especially in very warm weather or if there is excessive sweating. Limitation of salt intake is helpful when edema persists and the substitution of potassium salts may have some value.

If hydrothorax or ascites persists and is of considerable degree paracentesis will be found useful and may be repeated as often as necessary. Since the advent, however, of the stronger diuretics, tapping does not have to be resorted to as frequently as formerly. While Southey tubes to drain subcutaneous edema were described in 1877 and are always mentioned in articles on treatment of heart failure, they are but rarely needed, in fact I personally have never used them.

When dyspnea is marked, particularly if accompanied by marked cyanosis, inhalations of oxygen from a tent or by nasal catheter will usually lessen the cyanosis and often decrease the dyspnea.

Venesection (400–600 cc.) will sometimes be of value in relieving the dyspnea of myocardial insufficiency, but should be used only in the plethoric individual who shows venous and hepatic engorgement and in the case of acute pulmonary edema, characterized by urgent dyspnea, hacking irrepressible cough, frothy blood-tinged sputum, cyanosis, clammy skin, etc., which has not been relieved by immediate injection of morphine $\frac{1}{4}$ grain and atropine $\frac{1}{100}$ grain, repeated in twenty to thirty minutes.

The use of caffeine sodiobenzoate (1 ampule, 0.5 Gm. [$7\frac{1}{2}$ grains]) intravenously whenever there is evidence of a failing pulse, weak, rapid, thready, seems to be of value and may be frequently repeated to tide over a crisis. Similarly adrenalin injections—5 to 10 minims of 1:1000 solution intramuscularly—occasionally intravenously slowly as with 500 to 1000 cc. of 10 per cent glucose, and more rarely directly

into the heart after cardiac standstill, may act as a powerful stimulant in an emergency.

Quinidine must be mentioned in a review of the treatment of myocardial insufficiency though it will have but a small place therein. In the rare case when the heart rate in auricular fibrillation associated with cardiac decompensation cannot be properly slowed by digitalis, rest, etc., quinidine may be of some value though too much should not be expected in such a case. Likewise when heart failure supervenes on an attack of paroxysmal tachycardia, the use of quinidine to stop the attack and lessen the cardiac burden is definitely indicated. Quinidine, which is used as the salt, quinidine sulphate, causes toxic effects in some people even with small doses; therefore the patient should always be tested for idiosyncrasy by a small initial dose of 0.2 Gm. (3 grains). After that it may be given (usually in capsules) in a dose of 0.3 Gm. (5 grains) and thereafter 0.6 Gm. (10 grains) three times a day, if the toxic symptoms of diarrhea, nausea, vomiting, tinnitus, vertigo, headache, weakness, or fainting do not occur. In an emergency even larger doses may be used.

Today no discussion of the treatment of heart disease is complete without mention of total ablation of the thyroid as described by Blumgart and Levine and their coworkers. While the reported results have given rise to some promise and while the results we have had here in St. Louis have been a mixture of good and bad, we must still keep this procedure sub judice. My own feeling at present is that time will probably prove total thyroidectomy too radical and too uncertain a method to have much of a place in the treatment of myocardial insufficiency.

One phase of the treatment of myocardial insufficiency that is frequently completely overlooked and often given too little attention is the use of occupational therapy. The patient with heart disease is apt to be moody and introspective and needs an interest and outlet such as may be provided by occupational therapy. Reading was formerly the chief reliant of the cardiac patient but with the advent of radio broad-

casting a new large field for diversion was opened to the partially incapacitated person. But in addition to these measures, rightly included in occupational therapy, we have the stimulating handicrafts which widen the outlook and interest of the handicapped individual. Occupational therapy does more, however, by providing means for testing and training the patient with heart disease so that he may serve to his full capacity and not be handicapped by fears and prohibitions. Even in Class III patients, except in the very acute stages or in the terminal stage of heart disease, absolute rest is rarely required or desirable. In fact absolute physical rest with mental perturbation may and usually does result in greater strain on the circulation than mild physical activity and peace of mind so even in this group occupational therapy may be of great help.

Finally, a careful consideration of the entire social-economic status of the patient with heart disease must form a part of the scheme of treatment, for the difference between complete success and partial failure may depend upon a proper adjustment of these factors after the measures previously discussed have been provided.

CLINIC OF DR. SIDNEY I. SCHWAB

FROM THE NEUROPSYCHIATRIC SERVICE OF THE BARNES HOSPITAL,
WASHINGTON UNIVERSITY MEDICAL SCHOOL

NEUROSES AND PSYCHOSES AS THE GENERAL PRACTITIONER SEES THEM

THIS clinic attempts to do three things: first, to point out the present conception of the clinical types included under the terms neurosis and psychosis. Second, to suggest that the general practitioner or internist can recognize these diseases in their early and initial form. Third, to give brief clinical descriptions of cases which eventually tend to develop into one or another of the various types to which this classification applies.

The importance of attempting to describe these things from the standpoint of the general practitioner is obvious when the position which he occupies in relation to the general spread of illness is considered. The great percentage of all practitioners of medicine belong to the general practitioner class. From 60 to 70 per cent of all sick people can be roughly grouped as having a neurosis or psychosis either as a primary or secondary condition. That is to say in the great majority of sick people the preponderant clinical expressions and symptoms are due to the effect of disturbances, whatever their cause may be, on the functional integrity of the organism. In a very large proportion of all illness the effect of the illness is less to be noted in the organs and systems of the body than it is upon the individual as a whole. Illness of whatever nature shows its effect chiefly in disturbance of conduct, disturbance of feeling, disturbance in the capacity to

maintain a proper adjustment to the environment. From the standpoint of the patient whatever his description of his illness may be its effect upon him lies largely in a sense of incapacity or the demonstrable defect in his ability to work, in his inability to live up to the level of his social and economic necessities. For the patient this is the principal evidence of illness. The practitioner of medicine in this sense sees such instances of illness as a primary contact. Inasmuch as he represents by far the great majority of physicians he must necessarily see a great majority of such patients. These patients therefore represent by far the most important material for the incipency of the neurosis and psychosis.

The specialist in neuropsychiatry sees such cases, as a rule, as they filter through the preliminary stages of this and that specialist and finally as a sort of last resort are received into the small group of cases which can be taken care of by a comparatively small number of men, and can only be intelligently treated in comparatively small numbers. By that time in most instances the neurosis or psychosis is well fixed and crystallized and the therapeutic problem is one of prolonged and tedious treatment. It is important to get an understanding of these conditions as developed in the more specialistic levels into the levels represented by those physicians who in the nature of their work see such cases earlier and form frequently the first contacts with them. It is far more important, from the general welfare of the public and from the point of view of communal health, that the practitioner should grasp and understand the vital concept of the neurosis and psychosis than it is to develop a highly trained group of specialists who have neither the time nor the opportunity to take care of the great mass of people who are permanently or temporarily handicapped by these conditions. This is not to say that there should be any artificial limits in the number of neuropsychiatrists that are needed in any one community or that there should be any backward step in the primarily cultural, medical and postgraduate training of such a group. The point is made here, however, that until the non-

specialist group become infiltrated with the necessary and primary knowledge of these conditions the existence of a group of specialists will not begin to solve the neuropsychiatric problems in any community.

What medical training and education should seek is to provide for each student graduating from the medical school a grasp and insight into the mechanism of the neuroses and psychoses so that he will be able to see them as they first show themselves, to recognize them as clinical entities, and to treat them as such. The cases that do not respond to such treatment or those which represent the more complex situations will naturally drift after a while to the specialist, always marked, however, with the evidence and traces of an intelligent, well-informed and sympathetic contact of first instance. That is to say such would be the expected result if the simple and elementary principles underlying the origins and development of the neuroses and psychoses were understood and if the general practitioner as a part of his interest and activity could be persuaded to become as much interested in instances of these diseases as he is in the more common so-called "organical" conditions.

The training of the specialist is provided for sufficiently in our best medical schools or is in the course of being so provided. The training of the average medical man who is to become a general practitioner and internist is at present woefully deficient in this respect. This deficiency does not appear to be due to any lack of understanding of the importance of these conditions, but rather to a shifting emphasis from the more common states of illness to those of a rarer and specifically more interesting sort.

It is curious that the most common condition affecting mankind, that is, the defective working of his complete organism in terms of personal and environmental adjustment or in such distortions of his personality leading to the same result should be so completely ignored in the usual training of a medical student and should be so completely wanting at least in the sphere of interest in the average practitioner of medic-

inc. This criticism is not directed to the training in neurology and psychiatry in our best medical schools, which on the whole is ample enough, but to the fact that the knowledge gained there of these conditions is not carried through and out into the actual life and experience of the physician in general practice. There are many efforts to correct this seeming paradox by the organization of lectures, talks and postgraduate courses, by various societies and movements, mental hygiene, etc., but primarily the nucleus of the effort must be found in the early instruction of the medical student and by a resourceful and continuous effort to make of these conditions something as tangible, important and practicable as are the other branches of medicine.

There are several things that naturally spring out of this conception of the important rôle played by the neuroses and psychoses—one is that they are clinical entities—not perhaps as rigidly outlined as some other entities. The other is that they can be recognized in their incipency as the beginnings of other diseases can and that they form an important part of almost any kind of illness no matter what the nature of that illness may be. There is a psychiatric or neurotic background or even an extension of their mechanism expressed in symptoms in almost any one who is the victim of an organic change in his body as a whole. These neuroses or psychoses reactions or background may be expressed either as a local or as a general manifestation. Such manifestations may well be included in the classification of neuroses or psychoses as early or initial symptoms of these conditions. At times these are symptom reactions which are temporary and of an episode character and they disappear then as the general internal disease disappears or is cured. In other instances, however, they represent the very early beginnings of a later developed much more profoundly built up neurosis or psychosis.

How is it to be known that an individual who presents himself with complaints or symptoms usually described as localized in systems of his body is suffering from an early neurosis or incipient psychosis in spite of his obvious com-

plaints, as for example, headache, insomnia, indigestion, pain, muscular disability, etc.? It is necessary to know what these things are. Is it possible to reduce them to a more or less simple formula? The masking symptoms or complaints obliterate the underlying psychotic or neurotic manifestations. It is obvious that here the general practitioner could be most useful in finding out much more about the individual by seeking to extend his scrutiny beneath the description of the patient's own complaints.

The first thing is to get some notion of what psychoses and neuroses are. Is it possible to reduce them to a more or less simple formula containing insight into the mechanism, causes and developments?

A neurosis is in the first place a clinical syndrome, a built-up series of unusual and abnormal reactions. The patient is aware of this and he can describe his abnormal sensations, feelings, and can attach them to organs, functions and systems of his body. To the outsider, to his physician he may not present the appearance of a sick person, but to himself, which after all is the focal point of interest, he thinks, believes and is convinced that he is sick. On physical and laboratory examination there may be few or no data of an unusual or abnormal kind, certainly not those commonly associated with severe illness and as a rule the amount of disability which the patient is aware of is out of proportion entirely to the meager if any positive findings on examination. It is often this discrepancy which strikes the examiner as the most outstanding result of the examination. It is again this discrepancy which should suggest the existence of an illness not ordinarily defined in terms of objective changes. This discrepancy means in many instances the possibility of a neurosis. On the other hand no neurosis of any consequence escapes objective demonstrable clinical expressions of illness. The findings which can be determined by the ordinary physical, neurological or psychological studies are such as can be described and objectively determined. They consist of a group of symptoms that point to something that is called, and has been for a long time—

functional. A better term would be unphysiological. The paradox of a normal heart, for example, with tachycardia, a normal cardiographic pattern with dyspnea, pain, constriction about the chest and other indications of a defective heart mechanism. Fatigue in the presence of good muscular power. Visual deficiency in the face of normal retinal acuity and muscle findings. Headache and the accompanying invalidism with normal x-ray sinus examination. This discrepancy between findings and the burden of symptoms is generally striking and imposing. So much so that to the average physician the whole thing seems unreal. Here is a patient sick, incapacitated and handicapped and obviously in distress. What then is the chief mechanism which is capable of producing such a widespread disturbance in the functions, activities and in the physiological and chemicophysical organs, systems and organizations of the body? It must lie in the controlling and integrating mechanism of the body rather than in the structures themselves. It must be associated with causes which act particularly upon this mechanism and to which this mechanism is sensitive and for which such a system is automatically and physiologically planned or developed to respond. The nervous system and particularly its vegetative component represents in its distribution, control, widespread universal participation in all parts of the body an ideal mechanism to respond to what may be called emotional or feeling components. Perhaps the whole of this may be better understood if the term sensation is meant to be all-inclusive.

Emotion is the primary mechanism which actuates the total instinctive self-preservative functions of the body to act in forms of conduct which protect, safeguard, adjust, compromise and guard the personality against the whole of the environmental incidents, concurrences, happenings. When the resulting conduct is achieved then the emotion has fulfilled its function and the individual has transferred his emotion successfully in terms of conduct which has solved more or less completely and more or less successfully a particular situation. Such things are not neuroses situations. When

the conduct performs nothing tangible in terms of solution but results in nothing more than the production of what are called symptoms, then the situation is not in terms of an adjustable piece of conduct or performance, but the safeguarding lies in the organization of an illness under whose protection the patient is safe or guarded. He is so because he is sick and the inner conviction of illness defends him against a further difficulty in environment which in the first instance disturbed him. Fears, anxieties, apprehensions, states of panic are all noted as the precipitating agents of this disturbance of the individual's life. The organism spills out through the vascular system, glandular secretory system, energies which fail to produce adjustable conduct, but do produce disturbances in control and functional integration. Therefore the patient shows symptoms and findings demonstrable by the ordinary physical examination and in addition that inner state of tension resulting from emotional stimulation which has no avenue of external expression in terms of conduct. The sources of this distortion lie in conflicts, many of them unknown to the patient, many of them unconscious. Such conflicts have to do with the social, economic, erotic and personal life of the individual neurosis victim. This conception may be summarized in this way. The neuroses are clinical pictures, symptomatically organized, producing objectively recognizable physical abnormalities caused generally by disturbances in the function of an organ or system independent of gross anatomical structure changes. They arise from personal conflicts. They defend and protect the individual from the consequences of personal situations that he cannot solve other than through an illness. Most of these mechanisms are unconscious, though it is frequently impossible to draw a line between the two levels—the conscious and the unconscious.

This conception of the neuroses, which has been the outgrowth and development of many schools of thought and may be approached from many diversified types of etiology and mechanism, stands out as showing two things. First of all the reality of the neurosis and secondly the individuality of a

neurosis, that is to say, that each individual with a neurosis is an expression of that individual and no other, and consequently the study of a neurosis means primarily the study of the individual as a separate and distinct personality. This conception also provides for the general practitioner and internist a conception of the neuroses that is tangible and has its clinical expression that can be studied in the same way that any other disease can be. The symptoms and findings of such conditions can be tabulated and examinations made as part of the ordinary physical examinations, as in all instances of a neurosis is shown some disturbance in the function of the important and primary systems of the body. If no evidence of abnormal functioning is demonstrable then the chances of the patient having a neurosis are extremely small. The fact of the tachycardia, tremor, evidence of metabolic disturbance, and various kinds of pain, muscle disabilities of various sorts in the presence of negative laboratory and physical findings should not be passed by as something of no value, intangible and utterly beyond explanation, but should be understood as intimately as our knowledge provides of the general physical mechanism of the human body. In this sense they are symptoms and out of these symptoms are built clinical entities capable of tabulation and description.

A psychosis is a much more profound disturbance of the whole of a man. It is difficult to see evidence of the self-preservative instinct but rather the reverse is evident.

In the psychosis there is frequently definite organic changes in the structure of the nervous system, in the vascular system and in the neuron system of the brain. These produce alteration of conduct, disintegration and distortion of intellectual and emotional expressions all the way from serious deterioration and almost total intelligence defect to such a disturbance in mental organization that the individual is unable to make use of his knowledge, experience and articulate expression in line with his former intellectual and social level. Such gross disturbances are not difficult to recognize clinically and need not be described here in any detail. The so-called

"functional" psychoses are not removed in point of mechanism from the neuroses other than they involve less adaptation to experiences than a destructive and antagonistic attitude to them. The essential symptomatic expression of the emotionally derived reaction in terms of conduct may be found in both the neuroses and psychoses. The essential difference in a broad clinical aspect is that in a neurosis there is always an element of compromise and personal safeguarding while in the psychosis the examiner feels a sense of the destruction of personal adaptability, of a drive toward an injury to and final death of the personality. The victim of a delusional system is driven to acts or thoughts and plans of acts antagonistic to physiological safeguarding. The organized self-preservative mechanism so painfully built up through evolutionary experiences and reinforced by the individual's education and personal experience seem in many of the psychoses almost nonexistent and generally noneffective. For example, the obvious defective conditions of the functions of the body as a whole seen in depressive states producing nutritional defects of a serious nature cannot be viewed as in any way a safeguarding mechanism of the personality. The sense of unreality, so common in the symptomatology of an early psychosis, may be thought of as a sort of primary concept into the understanding of many a psychosis.

Aside from the study of content of consciousness, ideas, theories, concepts, etc., the victim of a psychosis presents many physical and symptomatic expressions of distorted physiological function; respiration, shallow, slow; nutritional defect; disturbance in the gastro-intestinal system, cardiac, vasomotor and excretory systems, etc. Metabolism is often disturbed and the psychotic as well as the neurosis patients are in the last analysis material for internal medical scrutiny as certainly the preliminary step toward understanding or anticipating the final psychotic crystallization into the chronic and inevitable hopeless state of the final stage of mental disease.

The psychoses in many ways show as initial symptoms

primitive and infantile types of conduct, reversion to primitive forms of escape, lethargy, stupor and sleep states, a feigning of death seen in animal-like stupors, a kind of situation hibernation. These early evidences of psychosis seen in the beginning of schizophrenia, for example, suggest that the sub-cortical mechanisms at the infantile level are working at the expense of the more cortical, more adult levels. The forgotten, submerged, primitive kinds of conduct cover the adult, more mature reactions, leading to nonorganized, unrelated infantile responses. The adult formulae are temporarily out. Among other things that can be noted, recorded and observed are frustration, the tendency to exist in the atmosphere and security of early experiences at the infant or child level, the building up of a conviction of hopelessness as far as the biological struggle to equalize the conflicts of a social, personal, economic, sexual kind. The outside world, the world of reality, becomes a distorted unreal world. Unreality becomes the characteristic of the world outside and reality of the world inside. There are the perverted sensory responses, hallucination, delusioned structures weighted with the tangibility and the realistic features of awareness. Infantile, childish material, the repressed experiences of that period are relived until they become the stuff of the activities of consciousness. Wishes, desires and day-dreaming phantasies become distorted into facts, the material of actual experience.

The psychosis and neurosis are characteristic clinical responses to difficult situations in the life of many individuals. The neuroses tend to tide them over under the protection of illness clinically recognizable and clinically demonstrable. The psychoses are likewise clinical responses of perhaps antagonistic types as far as the life situation as a whole is concerned. The psychoses are more profound personality disturbances and the mechanism of protection is less clear and has destruction rather than safeguarding as its characteristic.

It is also clear that in either group or in a combination of the two in one individual the conditions as such should not and cannot be divorced from the general aspect of internal

medicine. In any case of neurosis or psychosis the presence of actual disturbance in the functions and systems of the body should be inferred rather than ignored. The mind and the body are to be thought of as one and there is no disturbance of either that can leave the body as a whole unaffected. In other words the neurosis or psychosis or any combination of the two are primarily problems for the doctor interested in treating sick people and those whose function it is to take care of unselected groups of the sick in whatever social levels their activities are directed are the ones who see these cases in the earliest stages when understanding, guidance, explanation and simple medical planning may be effective in the prevention of the final crystallization of these states into chronic fixed and inelastic diseases of the personality.

Personality is defined here as simply the man in action—man living as a social being in a complicated difficult social structure. Sickness is one of the experiences that make him less fit to live in this respect and in particular illness of his nervous system producing primarily a less efficient integration as shown principally in less efficient conduct which is called the neurosis or psychosis. The general practitioner is logically the one who sees these things first, sees more of them, and sees them in the beginning, sees the early fragmentation of personality and should therefore be the one especially sensitive in a clinical receptive sense to the existence of these symptoms in his patients.

The last part of this will be devoted to a brief history of cases in which the essential neuroses or psychoses as clinical pictures are masked under the appearance of disease as evidenced by the presenting symptoms and complaints of the patient. These are the difficult problems which the practitioner has to face, namely, to see the early evidence of a neurosis or psychosis beneath the mask or screen of what at first appears to be gastro-intestinal, cardiac, respiratory or any other kind of illness.

CLINICAL EXAMPLES

Examples to illustrate the ideas of the neuroses and psychoses are not given as complete clinical reports but rather as sketches which attempt to reflect the clinical pictures as they might or have been presented to the internist or general practitioner as first instances, and as a contrast to the clinical pictures which they presented to the psychiatrist in a more completely developed type of disease.

Case I.—This is a married woman, thirty-four years of age. The marriage has been childless. The cause of the sterility is said to have been a congenitally small and pathological narrow vaginal outlet. As seen by the psychiatrist she presents the picture of a profound emotional disturbance with fears, apprehensions, anxieties and frequently occurring states of panic in which she is unable to carry out any practicable type of conduct in line with a situation necessitating some sort of action, that is, getting on a train, going to visit some one, meeting an appointment, etc. However she is always able to see a doctor and keep her appointment promptly. She has developed a feeling of security in the presence of a physician, whether her own or a stranger. It is noted that this patient is alert, intelligent, well-educated and responsive. She comes from people with fine cultural background and fine personal traditions. She married a man who is a chronic alcoholic.

Her past life has been filled with difficult situations—personal, family, domestic and economic. One brother is a manic-depressive. He lives with her in a distant city during his less excitable periods. Several members of her family have shown psychotic episodes, her father had several depressed episodes in one of which the writer was his physician.

Her chief complaints of a physical sort are tachycardia, loss of weight, and a history of numerous gastro-intestinal symptoms suggesting appendicitis, acute food poisoning, etc.

This sketches the situation as it now is—an individual

whose reactions are patterned and whose personality distortion reflects an emotional framework chiefly of the depressive type. Her total reaction has become so stereotyped that although she faces many different situations her response to them is generally psychotic. These responses are generally in the framework of a psychosis with definitely outlined clinical features resembling the depressed phase of a manic-depressive psychosis. The beginnings of the present situation were present when she was first seen by the family doctor at an early age. At that time she was an erratic, very intelligent child, given to emotional excessive reactions under very minimal stimuli. At an early age she was aware of the domestic conflicts between her parents. She was torn between her admiration for her father and her love for her very beautiful mother. At about the age of twelve her mother was divorced and she and her brother were in the custody of the mother.

The first of the acute gastro-intestinal attacks took place about this time and in each and all of these, extending through a period of many years, the diagnostic efforts were exclusively directed toward the gastric symptoms which tended to cover the underlying psychiatric situation almost completely. It was early noted by those about her that the most unusual features of these attacks were that the vomiting and diarrhea as well as the tachycardia and weakness appeared to subside with great promptness whenever a physician was present or upon her entrance to a hospital. She was many times taken to the hospital as an acute abdominal emergency. Several times she had been prepared for abdominal exploration and on each occasion just before the operation or upon her entrance to the hospital the acute gastro-intestinal symptoms stopped suddenly and the patient felt quite well. When she was twenty she had her first serious psychosis and was confined in a psychiatric institution for six months. This and a recent institutional experience of two months are the only sanatoria admissions.

Physical and neurological examination made of this patient just about two or three hours after the symptoms of her

latest gastro-intestinal attack ceased showed no significant findings. Outside of the slight loss of weight in the last two months she seemed physically well.

The point of this sketch lies chiefly in the first contact period with the general practitioner. It illustrates the vital importance of this early contact, presenting at least at that time an opportunity for an intensive study of this individual outside and apart from the acute abdominal symptoms for which in many instances the family physician had been called. It might have been obvious, though this is said with no degree of certainty, that the gastro-intestinal symptoms might have been recognized as purely functional or an emotional escape through which the pent up feelings gained in this way some sort of physical expression. Perhaps in this as in other cases this was understood by the physicians who saw her in her early years, but the fact remains, however, that whether recognized or not nothing was done in the way of explanation, guidance or change in the environmental relation of this patient to alter in any way the conditions which produced not merely the gastro-intestinal symptoms but laid the foundation for the future development of a psychosis. This patient has been examined at least fifteen times in various hospitals and clinics throughout the country for evidence of gastro-intestinal disease. She has been x-rayed many times. Nothing ever was found to account for the gastric symptoms. All other examinations have been equally without findings.

It is evident in this short account that the period of greatest therapeutic possibility was during the years of early medical contacts. These contacts naturally with physicians who had no particular specialistic knowledge of psychiatry or neurology. Yet there is the possibility that if the importance of understanding something about the personality of the individual who was sick had permeated down through the levels of sickness caused by so-called "organic" causes this individual might have been seen, dimly outlined it is true, as the psychiatric figure which she developed into at the age of twenty with a psychosis which at that time was manifesting itself and

crystallizing into the clinically patterned form which she shows at the present time.

Case II.—This is a man forty-five years old, who came into the Barnes Hospital after a preliminary office visit with a chief complaint of shaking of the right hand. This goes back some ten or twelve years. It had been diagnosed as paralysis agitans by a number of doctors. The patient is an intelligent well-trained minister who has obtained a Ph.D. in English at a western university. The physical examinations at Barnes are essentially negative. In addition to the tremor of the hand a definite hemihypesthesia with sharp midline distribution from the top of the head, bisecting with accuracy the body half is found. A history of an automobile accident and compensation involvement is obtained. It is noted that the tremor in the hand becomes much more marked when the compensation question is gone into and when the details of the litigation are mentioned. The tremor was not thought to be of the parkinsonian type and the diagnosis of a neurosis with hysterical features was made. In the short time the patient was at the hospital many instances of conflict, personal disappointments and other difficulties going back to his early college years, his early adolescent and preadolescent years were obtained. There was also the question of honesty in handling funds which were entrusted to him in one of his college positions. The most outstanding of the adult characteristics as shown in the development of symptoms were the accumulation of conflicts, the difficulty in personal adjustment, the frustration of his aims and objectives and resulting dissatisfactions. Patient feels deeply that he was trained and prepared for important teaching positions, as an academic figure and as a religious leader. For each and all of these things his record was always a failure. Behind all of this was his domestic conflict and the necessity he feels of being at home as little as possible. The precipitating factor in his present neurosis was the slight trauma sustained in the automobile accident. Tremor, muscular and vocal fatigue with the hemiplegia are

the objective indications of his neurosis. Here then is a well-developed picture of a neurosis developing in late adult life precipitated by a trauma with litigation features.

Obviously this clinical reaction has its origin, possibilities and roots in early childhood and adolescence. There is only vague information of his early illnesses and only the faintest hints at early medical contacts. There were the usual childhood diseases with symptoms evidently always exaggerated. The environmental influences in which this boy grew up, the conflicts between his own parents, the desire to escape their fate and their low social and economic attainments through education and training could no doubt have been ascertained if such things could be associated with or weighed by medical importance. There must have been many opportunities in the early medical contacts where identification of personal characteristics as favoring the development of a future neurosis could have been made. Even so brief a study of his childhood and adolescent life as could be made in the hospital showed that in almost every difficult situation in life, in almost any situation of a conflict nature, the patient was unable to realistically face them and even in his early childhood had taken refuge in symptoms as a conscious effort to escape responsibility, to escape effort and eventually to escape criticism. These early patterned activities are the stuff out of which the neurosis of an adult type was fashioned. The point is stressed that the possible recognition of these things might have been of value in directing this patient's training and early career in school and college. It is admitted that many of these things were not capable of being corrected, but it is also possible that if this patient had in his early years been able to see himself as he really was and if the patterns of action were noted by his physician as a part of the personal study of this individual then at least this individual might have had an understanding by which he could have modified his actions on a more adjustable level.

Case III.—A childless woman, forty-one years of age, married thirteen years. Her husband is a successful business

man and while he has had to work hard there has been little economic stress in the lives of these two people, and certainly none in the last few years.

When first seen she was obviously depressed, inarticulate, introverted, anxious and not a little suspicious. She did not want to see me or any other physician, saying with a good deal of conviction that her sickness was not such that any doctor could either cure or help. Her chief complaints are rapid beating of the heart with sensations of jerking, fatigue, inability to sleep and a state of utter emotional indifference to her husband, parents, relatives and friends. She believes that she has an incurable disease and that she will soon be dead or spend the rest of her life—which will not be long—away from her husband in some place which she is unwilling or unable to describe. She admits that she always had fears of sickness and fears of doctors with whom she has always associated the dire results of illness which in her case seems to have been centered around the fear of tuberculosis.

She was persuaded to enter the Barnes Hospital which she reluctantly did, saying she did so only because her husband insisted. The neurological and general physical examinations showed only insignificant findings—slight tachycardia, some loss of weight, great fatigue on slight muscular effort. Cardio-graphic studies, basal metabolism, etc., were normal. She showed no gross intellectual defect, but was emotionally on a low level, showing feeling only when she described her symptoms, chiefly pertaining to her heart and lungs. Then she would become momentarily more alert and animated. It was clear that in the fancied presence of these severe diseases, the solution of her difficulties was to be met. The wish to be dead was to be accomplished through the natural process of a fatal illness and not through suicide. She would conclude almost any conversation with such phrases as, "I have been such a failure in the past that things will never be the same." "I can never be what I should be." "I am indifferent to my husband as I am to others." She lists the diseases she fears most as tuberculosis, heart disease, cancer of the breast, fear

of choking to death. The fear of these diseases and the wish to be dead of them represents one of the many conflicts which distorted the emotional and intellectual life of this patient. It is evident also that the feeling of an almost total inadequacy and incapacity had developed out of the beginnings of this process extending back to the early years of her married life and back of that to her young girlhood and childhood. She described many fears, of high places, of going to pieces, of not accomplishing things, of making up her mind, of arriving at decisions, of meeting strange people, of being hostess at her home to the friends of her husband. He in order to protect her took on himself most of the duties and responsibilities until she became completely dependent upon him—thus increasing her sense of personal futility and emphasizing her sense of personal inferiority (this is only the briefest sketch of the many mechanisms at work in producing a psychosis). Depression, listlessness, emotional indifference, a state of recessiveness, a total loss of interest in the external world, introversion, and a negativistic attitude resulted. A wish to die instead of to live and a constant fear of disease. Back of all the mental and emotional distortions were the constant symptomatic picture of heart, lungs, eyes, gastro-intestinal distress, weakness, loss of weight, etc. These are the common descriptive terms of almost any kind of illness and were the masking of serious personality difficulties by evidence pointing superficially to well-recognized organic disturbances.

The first contacts of this patient with the family physician were in the nature of acute throat conditions. There were many instances of tonsillar infections in which choking sensations were much exaggerated. There were many examinations of her heart and several remembered bits of medical caution about the effect of these infections upon the heart. Tonsillectomy was advised but was never done because of her fear of choking to death. A period of lung symptoms with the phantom of tuberculosis was remembered as a pretty constant experience of her late childhood and adolescence.

She grew up in a very rigid, tight, inelastic atmosphere,

narrowly religious, a household permeated with a sense of obligation and duty, a masterful father and a dominated mother. She had little freedom, only selected playmates, and no social contacts outside a few family associates. No sex instruction and no questions allowed. This with many other questions vital to a growing adolescent girl were taboo. Marriage was to her a prospectively terrible experience, which, as a matter of fact, she postponed several times in states of panic and fear. It is not necessary to more than mention the framework of this patient's early years to suggest that there were the beginnings of the psychosis described in the latest psychiatric contact.

It would seem evident that the opportunity was presented to the general practitioner who first took care of this patient in those earliest years to at least have identified the personality characteristics of this type of child as being the stuff out of which a future neurosis or psychosis might develop. Very likely the physician vaguely did recognize this and felt powerless to do anything about it. Here again the opportunity at least is stressed.

The limitation of space in a clinic of this kind permits only the mention of two other cases which are illustrative of the main concepts of this clinic.

Case IV.—A young girl of twenty-five. Her chief complaint was that she blushed at inopportune moments, especially when the situation of itself contained no incident or occasion for blushing. When she felt the heat and saw the redness of her face in such moments she felt a sensation of weakness, confusion, could scarcely speak, felt foolish and powerless, and above all had the sensation that every one was observing her with not only curiosity but critically. This idea became so obsessive that she gave up a promising position for which she was carefully trained and entered a school for another kind of work, less to her liking and of a lower level of effort.

The neurological and physical examination of this young

woman was found to be within the normal other than a vasomotor instability of the skin over a large part of her body, and very marked unusual dermatographic responses.

An early sexual experience of an emotionally shocking character was regarded as the precipitating factor in conditioning the blushing response. Much further back in the patient's life were found many instances in which feelings of shame, guilt and sin resulted. The physical beauty of an elder sister as contrasted with her own unattractiveness made her very early self-conscious about her own appearance. Early defects in her teeth, which later were corrected, served to accentuate the feeling of her own physical self as an ever-present fact in her consciousness. The foundation of ideas of reference was thus early laid and the obsessive ideas associated with blushing and the beginnings of the ideas of persecution and of ill-defined delusions of a paranoid type developed inevitably from these early and at that time insignificant beginnings.

Case V.—The last case is one of recurrent depressive states in a young woman, a college graduate, trained as a teacher, and forced to give up active work by the constantly recurring depressed states. These produced a more or less constant state of a sense of growing incapacity and states in which confusion and a sense of unreality were becoming increasingly evident and constant. Associated with this was the usual emotional dulling repeated so often in the history of the early developing psychosis. The interesting point in this history is that at a very early age the patient had an attack of estivo-autumnal malaria, and it was for the treatment of this condition that her earliest medical contacts were made. Beneath and behind this actual organic disease was the growing environmental influence of a household disturbed by the conflict between a much beloved mother and a hard overdisciplined father. The death of the mother and a remarriage to a woman much inferior, socially and culturally, to say nothing of other qualities. An early step-mother situa-

tion in reference particularly to this girl. Years of extraordinary effort to attain the highest marks in school as a compensation for the unfairness and injustice at home. This effort was made in spite of the continuing periodic attacks of the malaria and against the periodic fatigue and ill-being characteristic of this disease.

It is clear again in such a case how definite is the opportunity of the practitioner to sense, to know and to identify the setting out of which the psychosis of later years developed.

These cases are picked at random representing only an insignificant percentage of possible material. Any general practitioner's practice is filled with like instances. For him is the opportunity for neuropsychiatric insight and opportunity for the prevention or alleviation of future neuropsychiatric diseases. There is no way of fulfilling the social obligations which his peculiar and traditional type of medical practice puts upon him other than to study not only sickness but the sick person. The purpose of this clinic was to point this out and the clinical sketches were devised to make this more realistic.

In conclusion the author feels that what he has said is what every general practitioner already knows—possibly better than he does.

CLINIC OF DR. P. E. KUBITSCHKE

CHILD GUIDANCE DEPARTMENT, ST. LOUIS CHILDREN'S
HOSPITAL

THE DIAGNOSIS AND TREATMENT OF FUNCTIONAL DISORDERS OF CHILDREN

THE term "functional disorder" is attributed to those who show some type of physical disturbance, either subjective or objective, in whom no organic factors which could be held a responsible cause for the difficulty, can be demonstrated. Such manifestations are numerous and range from purely subjective complaints such as headache and abdominal pain, to the more definite physical disturbances such as enuresis, fecal incontinence, nausea and vomiting, stuttering, sleep disturbances, etc., and the more striking physical manifestations of various tics and hysterical paralyses.

The material on which this paper is based is taken largely from cases studied at the Child Guidance Clinic in St. Louis, a department of Children's Hospital, which has been in operation with its present personnel for eight years. Some 300 children have been seen annually for examination and treatment. These children, ranging in age from three to seventeen years, are of the so-called "normal" group, that is, the feeble-minded, epileptics, and those suffering from primary organic disease of the nervous system are excluded. They are referred to the clinic because they have become serious behavior problems at home, in school or in the community. While they are brought to the clinic primarily because of problems of behavior, approximately 40 per cent show some definite physical manifestations of nervousness. These include thumb-sucking, masturbation, hair-pulling, various tics, sleep disturbance, psychic vomiting, enuresis, fecal incontinence, stammering,

phobias, obsessions and hysterical reactions such as paralysis, fainting attacks, aphonias and blindness.

DIAGNOSIS OF FUNCTIONAL DISORDERS

The clinic study of problem children includes: (1) a study of the family background, medical and developmental history of the child, a long section picture in which heredity and environment are seen in relation to each other. (2) Psychological tests which give valuable information concerning the general level of mentality, specific handicaps, such as reading disabilities, and special abilities. (3) General physical examination and special examinations where indicated. (4) Neuropsychiatric study.

Investigation on this broad scope has shown significant relationships between emotional disturbances, behavior and functional disorders of decided value in the diagnosis and treatment of functional disorders. A brief survey of the nature of behavior, social as well as visceral, will assist in understanding this point.

All human beings are born with identical instinctive drives and emotional needs. Their primary instinctive drives are for self-preservation and for racial preservation or reproduction. Their primary emotional needs, which they constantly seek to satisfy are for security and social acceptance. While the instinctive drives and emotional needs of children are uniformly the same, the equipment which they possess and on which they depend to satisfy their needs show a remarkable degree of variation. That is, some inherit a pattern of growth which destines them to be feeble-minded while others possess the capacity for average or superior intellect. Others inherit a pattern of physical structure which places them at a serious disadvantage with their more vigorous associates. An equally great degree of variation probably exists in the less tangible but important factor which we may call emotional or nervous stability. Again there are those who, although potentially normal, from a hereditary point of view, suffer a degree of damage through trauma, infections and toxemias, which

seriously interferes with their development and impairs their ability to successfully meet life requirements.

Behavior is the physical manifestation of the individual's effort to satisfy its instinctive and emotional drives in whatever environment it finds itself. Its success in accomplishing this end depends on two factors: (a) its ability, physical and mental, and (b) the manner in which it has learned to use these abilities. The world is a competitive world and the child finds itself in a competitive position from an early age. It is only when the child finds itself subjected to a very severe shock, which seriously threatens its security, or to prolonged failure, that an emotional disturbance sufficient to produce a chronic behavior problem or a physical functional disorder, or both, results.

Seen from this point of view a functional disorder may then be considered as a symptom of increased nervous tension which in turn is the product of acute or chronic insecurity. The child's life can be divided, for purpose of study, into four main spheres: (a) home life, (b) scholastic life, (c) social and physical competitive life, and (d) sphere of physical growth and health. No child is or need be uniformly secure and successful in all these spheres but serious failure or fear of failure over a long period of time in one or more may be sufficient to produce decided emotional disturbance and a functional disorder. On the other hand those who are happy and reasonably secure and successful in these spheres do not suffer from functional disorders. This is an important point in the differential diagnosis of functional disorders. The whole developmental history of the child must be considered and it is extremely rare that functional disturbances develop in those who have made good adjustments in these spheres.

The more common causes of unsuccessful progress and disturbances of the child's emotional state may be summarized as follows:

- (1) In home sphere—(1) Broken homes, incompatibility and friction between parents. (2) Illness or death of parents.
- (3) Overanxiety and overprotection of the child by parents.

(4) Lack of affection and resentment of children because of poor ability. (5) Excessive partiality to other children and unfavorable comparison. A child subjected to any of the above situations for a relatively long period of time may develop not only a feeling of insecurity and resentment in relation to the home situation but carry over such feelings in its associations outside of the home, where they act as handicaps to his successful progress in group and school life.

(B) In the scholastic sphere—(1) Emotional disturbances and visceral disorders during the first few months of attendance at school are common. Sleep disturbance, enuresis and vomiting are the most common types of reactions observed. They occur particularly in cases of the only child who has been overprotected in its home and has had little opportunity for a normal competitive association with neighborhood children between the ages of three and five. The sudden transition from association with adults in the home to a strange school group is often sufficient to produce a marked degree of instability which in the majority of cases subsides in the course of a month or two. (2) Failure to progress in school work with subsequent criticism from teacher and home due to inferior mental ability, or frequent absences from school resulting from illnesses. (3) Failure to make normal scholastic progress as a result of special handicap in language work, *i. e.*, inability to learn to read or spell although general level of intelligence is normal. This type of difficulty manifests itself particularly in second, third and fourth grade and it occurs chiefly in those who show some evidence of lack of cerebral dominance or the so-called "inter-grade-handed" individuals. We have seen more than 300 cases of this type of handicap in the past five years and while this difficulty is due to a basic organic factor, the insecurity and emotional disturbances resulting from the persistent scholastic difficulty and failure frequently produce marked functional and visceral disorders. For example—a nine-year-old boy, who had shown increasing nervousness in the past two years, was examined at pediatric clinic. Infected tonsils

were found and tonsillectomy and adenectomy done. Patient made good recovery, but soon after return home developed a throat tic. He was then referred for psychiatric study where careful inquiry of life history showed he had made very satisfactory development until his second year in school, when he had increasing difficulty in his work and nervous manifestations soon followed and persisted. He had been placed on condition into third grade because of his good general ability, had failed in third grade work and was again doing failing work his second year in third grade when taken for medical examination. In spite of normal intelligence it was found that patient's reading and spelling ability were only at first grade level. He showed tendencies to reversal and other physical signs of intergrade handedness which clearly showed him to be a reading disability case. The mother was left-handed. Patient was put on program of remedial training, given an understanding of the nature of his difficulty and his nervous manifestations rapidly decreased. His tics returned two weeks before the end of the school year when he was told that although his work had improved a great deal, he was still unable to do satisfactory language work and it would be necessary to again repeat third grade.

A girl, age eleven, was admitted for study because of the development of attacks during which she suddenly stiffened out and slid from her seat to the floor, then assumed a tonic flexure attitude and emitted a peculiar whistling cry which continued at times for several minutes. The seizures, which had started two months prior to admission, at first occurred only at school, later occurred at home. Sleep was undisturbed, there was no actual loss of consciousness, no actual convulsive reactions and no after-period of headache or drowsiness. The girl was retarded in both physical and intellectual development, unattractive in appearance. Her parents were critical of her slow progress, made her do long periods of home work and she was unfavorably compared at school and home with her more capable brother and sister. She was in fourth grade in school, doing poor work and her nine-year-old sister was

doing good work in the same class. Earlier in the school year a classmate had suffered from convulsive seizures and was removed from school. The patient had witnessed several of these "shaking attacks" as she called them. Attacks quickly ceased while in the hospital but recurred when parents visited. Here the purpose, as well as the origin, of the functional disorder is obvious.

(C) The social and physical sphere—functional disorders primarily related to failure in this phase of development occur chiefly after ten years of age. The more common basic factors are (1) serious handicap in material or social advantages, especially among girls. (2) Inferior physical ability, especially among boys. (3) Special physical disabilities such as residuals of poliomyelitis, blindness, severe acne, etc.

A boy, age twelve, complained of attacks of gastro-intestinal pain, later phobias of being poisoned developed. For a month he had eaten only food which he took directly from freshly opened cans or which he bought in cellophane-wrapped packages at the store. He had been out of school for several months, sleep was badly disturbed and he had developed some facial tics. Physical status was essentially negative aside from a mild degree of malnutrition. History revealed that patient had been a nervous child from infancy on, had little opportunity for play with children, was popular and attractive to adults because of his intellectual precocity. He was of superior intellect, had been an outstanding scholar and until the past year had led his class. He was small, lightly built and had practically no knowledge of normal physical competitive skills, could not swim, had never played ball, marbles, skated and was extremely apprehensive of any physical combat. His keen intellect made him more sensitive to his inadequacies. This history survey resulted in the direction of treatment to an intensive physical development program rather than against his symptoms. He vigorously protested at first, but as skill and ability developed, interest followed, with most gratifying results.

(D) In the sphere of physical growth and health—handicaps of sufficient intensity to produce serious emotional and functional disorders fall chiefly in one of the three following groups.

1. Those whose patterns of physical growth have been such as to make them conspicuous and place them at a disadvantage in comparison with other children. In this group are found those who are unusually large or conspicuously small, those handicapped by physical malformations or deformities resulting from spastic plegias, infantile paralysis, etc., unusual rapidity or retardation in sexual development and marked adiposity. Any marked deviation may produce a degree of anxiety and introspection which seriously interferes with normal emotional health and successful adaptation.

2. Those who have been subjected to experiences of illness which has left chronic feeling of anxiety for their present and future health. Among this group cardiac cases are particularly prevalent.

3. Those who have become excessively introspective and apprehensive about their health, chiefly as a result of association with neurotic adults.

A ten-year-old girl was seen about a year ago because of persistent attacks of difficulty in breathing. She had been under treatment at pediatric clinic for some time. Complete physical examination including x-ray studies failed to show any physical causes for her difficulty. It was found that she lived alone with her mother who for years had suffered from poor health. The father had died some four years previously of tuberculosis. The child slept with the mother and the mother had so-called "spells" when she too had trouble getting her breath. The atmosphere of the home was drab. The child, although she had made normal school progress, had little opportunity for normal neighborhood play or physical activity because of her so-called "spells" and mother's anxiety about her health. She was subject to chronic sleep disturbance and frequently awakened at night in one of her difficult breathing attacks.

Another boy, age thirteen, suffered from enuresis, nightmares and occasional sleep-walking and attacks of palpitation. These symptoms developed after a medical examination two years earlier at which time he had been told by the doctor that he had leakage of the heart. He had been taken out of school, kept at home in bed for a period of a month and thereafter his physical activity had been sharply restricted. Patient had been out of school much of the time from that date and developed strong introspective tendencies and was in a chronically apprehensive, unhappy emotional state. It was found that patient's actual physical condition was such that he could well participate in normal physical activities. His response to a program which provided these together with measures to counteract sleep disturbance, enuresis and nervous tension was most gratifying.

TREATMENT OF FUNCTIONAL DISORDERS

The treatment of functional disturbances must be directed at: (a) the visceral disturbances or symptomatic level and (b) the correction of the basic causes responsible for the production of the emotional tension. No detailed discussion of treatment program for the wide variety of functional disturbances can be included in this paper. The important point of emphasis is that the visceral disorders be recognized as symptoms of an underlying difficulty so that treatment is not limited to the correction of the nervous manifestations. A few general principles should be kept in mind. (1) The patient has been subjected to emotional disturbances for a considerable period of time, nervous irritability is increased and consequently the intelligent use of sedative medication is extremely valuable, particularly in the earlier stages of treatment. This is especially true when as is often the case the emotional unrest continues through the night interfering with normal depth of sleep and interfering with the natural phase of rest and recuperation. (2) An attitude of sympathetic interest and inquiry beyond the physical complaints into the child's life at home, situation at school, opportunities and

interest in neighborhood associations, will do much to gain the confidence of the child and will also give the physician considerable information as to the sphere in which the child's security has been chiefly threatened. (3) Functional disorders are usually the result of a long period of emotional unrest, consequently their response to treatment is often slow. While the child should be assured as to the ability to cure the difficulty, the time element that may be required and the occurrence of occasional relapses should be frankly discussed with him. Too often the child is subjected to increased anxiety when treatment measures are not immediately or permanently successful.

Treatment measures directed to the basic causes must be determined by the factors revealed in the environmental study. In the case of the girl with the breathing difficulty, little could be done to change the neurotic nature of the mother, however, certain measures were outlined which at least diluted the intensity of the influence of the mother. It was insisted that patient must sleep alone and that she be provided with roller skates and spend at least one hour a day in out-of-door play. The mother accepted this on the basis of the child's need for fresh air and exercise. In addition to this it provided further separation from the mother and opportunity for play association with neighborhood children. In general it has been found that when parents realize the need of freedom from excessive criticism, approval for effort and the opportunity for association with other children, they will cooperate in planning to meet these needs. In a general way the same principle applies for assisting the child to overcome its handicaps in the other spheres of development—scholastic, physical and social. There are many cases in which the handicaps are of such a nature that they cannot be successfully overcome, such as seriously defective vision, defective intelligence, cardiac lesions, endocrine disturbance, etc. In such cases the problem lies in finding satisfying and constructive outlets to compensate for existing handicaps.

CLINIC OF DR. CHARLES H. EYERMANN

FROM THE DEPARTMENT OF MEDICINE, WASHINGTON UNIVERSITY SCHOOL OF MEDICINE AND THE BARNES HOSPITAL

THE TREATMENT OF BRONCHIAL ASTHMA

As early as 1830, clinicians noted that paroxysms of bronchial asthma followed exposure to specific substances. No importance was attached to these observations until Meltzer,¹ in 1910, interpreted the asthmatic paroxysm as a phenomenon of anaphylaxis. As a result of observations in the clinic and in the experimental laboratory with this principle in mind, the therapeutic effectiveness in bronchial asthma has increased from 5 per cent to better than 50 per cent.

Since asthma means gasping, in the course of time it has been applied to a great number of diverse clinical conditions in which dyspnea is the presenting symptom. Such terms as cardiac, renal, thymic, and uremic asthma, and also asthmatic bronchitis have developed. Our present knowledge allows us to define bronchial, spasmodic, or allergic asthma as a recurrent paroxysmal dyspnea, particularly manifest in the expiratory phase, due to an allergic reaction in the bronchioles resulting from the absorption of a substance to which the individual is hypersensitive. This excludes those forms of dyspnea with wheezing breath sounds which mimic allergic asthma, such as, certain types of cardiac decompensation, bronchial stenosis from foreign bodies, or tumors, mediastinal and pulmonary disease. Neither wheezing breath sounds nor dyspnea connote hypersensitiveness. To avoid confusion, it would be desirable to indicate the clinical manifestation of hypersensitiveness as allergic asthma rather than the term

bronchial or spasmodic asthma by which most clinicians of the present day indicate these symptoms.

The mechanism of the attack has been a matter of controversy for many years. Bronchospasm has been considered the cause since earliest times and the discovery of the anaphylactic phenomenon emphasized this factor. Further support for the bronchospastic mechanism is had by the experimental data which indicates that bronchial constriction and probably secretion from the mucous glands can be initiated by stimulation of the vagus nerve. Edema, however, is the essential reaction in hay fever and vasomotor rhinitis, which is so frequently associated with asthma, and also in the allergic reaction in the skin, so that it seems logical to infer that edema of the bronchial wall may be the dominant cause. Further, this has been observed by bronchoscopic examination during asthmatic attacks and clinical experience with epinephrine supports the belief that edema rather than spasm is the dominant factor. In addition bronchial plugging with viscid exudate, which has some support by the appearance of the roentgenographic chest plate, with lipiodol visualization during an asthmatic paroxysm, must also be considered. Whether these reactions are brought about in all instances by central or peripheral stimulation of a circulating or contacting allergen, or by vagus stimulation, one or both, remains for further study to elucidate.

The clinical study of allergic asthma has established the following criteria for its recognition:² (1) There are allergic manifestations in the antecedents. (2) Other manifestations of allergy occur in the patient. (3) It usually starts in early life—the onset past the age of fifty is infrequent. (4) It is, in the beginning, chiefly paroxysmal in nature. Between attacks, for indefinite periods the patient is practically normal, presenting neither subjective nor objective symptoms or signs. As the condition progresses, attacks follow more rapidly, and complicating bronchitis and emphysema eliminate all free intervals. (5) Acute paroxysms are often preceded by symptoms of hypersensitiveness involving other systems, such as

hay fever, vasomotor rhinitis, gastro-intestinal disturbances, urticaria, and angioneurotic edema. (6) The most severe attacks occur while trying to sleep. (7) A tendency to periodicity in relation to the hour of the day or night, day of week, or season of the year. (8) Orthopnea is a prominent feature, even between paroxysms. (9) Emphysema is the usual finding; present at first only during the acute attacks, it later becomes a permanent feature. (10) Epinephrine will control the dyspnea in all except the most unusual instance. (11) Sputum collected during or shortly after an attack may show Curschmann's spirals, Charcot-Leyden crystals and almost invariably eosinophils. The coincident blood and sputum eosinophilia is almost pathognomonic. (12) The occurrence of positive skin tests. They are not the chief reliance of the etiologic diagnosis as allergic asthma may occur with negative skin tests.

There is no essential difference in the treatment of bronchial (allergic) asthma in the child from that in the adult. The fundamental requisite in either instance is the identification of the offending allergen, followed by its complete removal from the environment or the diet. There is no standardized treatment. The method of treatment is determined by the etiologic agents. One treats an individual and not a case of allergic asthma.

The treatment of allergic asthma resolves itself into the management of the asthmatic attack and the search for the fundamental cause. The treatment of the asthmatic attack can be undertaken without knowledge of its etiology, but the responsibility of the physician is not fulfilled with its control. All future endeavor should be directed toward the prevention of subsequent attacks.

The successful management of the acute severe paroxysm of allergic asthma is dependent upon the subcutaneous use of epinephrine hydrochloride 1:1000, probably better known as adrenalin. Except in those who have developed a tolerance for it, doses up to 0.3 cc. are as effective as larger ones, without the unpleasant and sometimes alarming side actions of the larger doses. A satisfactory method of using the drug is

to fill the syringe with 0.5 cc. more or less, and with the syringe remaining in place, to inject 1 minim or 0.1 cc. a minute until the attack begins to subside or until beginning physiological effect is noted by pallor, which is often first seen about the nose by tangential light, by fibrillary muscle tremor, or by palpitation. When physiological effect is obtained, there is no need to administer more epinephrine even if there has been no improvement in the attack. In an emergency, however, one need not be concerned with overdosing, and enough should be given to produce the desired effect. In some instances of status asthmaticus, it has been possible to give several cubic centimeters of adrenalin by the slow continuous subcutaneous administration without inducing side effects.

Ephedrine and the oral inhalation of adrenalin 1:100 solution by means of an all-glass nebulizer producing a very fine spray, are useful only for mild attacks; attacks which are more a discomfort than a paroxysm of bronchospasm. In children, the cough is readily controlled by codeine when mere change of environment or avoidance of specific foods plus subcutaneous adrenalin is not entirely effective.

The management of the frequently repeated paroxysm of allergic asthma revolves about the search for the causative agent, the administration of adrenalin and sedatives and maintaining the nutritional state, until the etiological factor is found. The prolonged or continuous attack is often benefited by change to an environment where all the usual causative allergens are absent. Experience has shown that admittance to a hospital in which the usual extrinsic causes (feathers, orris root, wool, cotton seed, insecticides, animal pets, house dust) are avoided brings about cessation of attacks within five days. This, in itself, is diagnostic and points to an environmental factor as the cause. Some cases require, in addition, short periods of starvation or some type of elimination diet before relief is obtained. In these instances, one assumes that an ingestant may be an added etiologic factor.

When dietary manipulations and environmental change aided by the subcutaneous administration of adrenalin do not

about a cessation of the paroxysms, sedatives are necessary. They are of particular benefit when there is extreme pulmonary dilatation as shown by great hyperresonance at the apex and absence of downward expansion of the lungs by percussion. In these instances the slightest exertion, eating, talking, or cough increases the already existing discomfort. The effect of epinephrine becomes transitory even with increasing dosage and shorter intervals of administration. The therapeutic indication is absolute rest and control of the

When cough is not a prominent part of the symptomatic picture, sedatives of the hypnotic series are helpful when given for their purely physiological effect, provided there is no sensitization to the drug. When the pulmonary dilatation is accompanied by frequent cough, morphine or pantopon is useful in repeated doses, provided no idiosyncrasy exists. *These drugs never be given in the customary dose of 0.015 Gm. ($\frac{1}{4}$ grain), or 0.01 Gm. ($\frac{1}{6}$ grain) respectively.* When employing these drugs the respiratory rate must not decrease below 20 per cent, and a fluid intake of 3000 cc. for twenty-four hours must be maintained (sputum cannot liquefy in a dehydrated patient). For the adult, a satisfactory method is to give morphine 0.004 Gm. ($\frac{1}{16}$ grain), or 0.005 Gm. ($\frac{1}{12}$ grain) hypodermically. If the cough or restlessness is not allayed after several injections at three- to four-hour intervals, the dose may be cautiously increased to 0.008 Gm. ($\frac{1}{8}$ grain), or 0.01 Gm. ($\frac{1}{6}$ grain)—but never at any time allowing the respiratory rate to fall below 20 per minute or the patient to become more than lightly narcotized. It is unusual to require more than 0.015 Gm. ($\frac{1}{4}$ grain) morphine, or 0.01 Gm. ($\frac{1}{6}$ grain) pantopon during the twenty-four hours. In some cases, better results are obtained by combining the morphine or pantopon with small doses of adrenalin. This condition also requires individualization of treatment. With the administration of morphine, glucose solution should be given orally and normal saline solution subcutaneously to dilute the adrenalin (5 to 1000 cc.) can be advantageously

added. The amount of fluids given should be governed by the degree of dehydration. Coexisting abdominal distention should be relieved by enemata as soon as the condition of the patient permits, and a small catheter left in the rectum to allow of the easy expulsion of gas.

Many variants³ of the therapeutics for this clinical phase of allergic asthma are proposed by clinicians with extensive experience in the care of these cases. These will be found satisfactory for selected cases. As yet no one method is applicable in all instances. They usually concern the type, dosage, and technical administration of their favorite sedatives, and the simultaneous management of the associated dehydration and nutritional state.

Treatment of the allergic state responsible for the acute paroxysm requires a study of the patient as a whole, considering his heredity, the environment and the peculiarities, and the dietary habits, correcting abnormalities as found by physical and laboratory examinations and the interpretation of observed reactions. One needs not only a thorough knowledge of internal medicine and its diagnostic handmaiden allergy, but also an expanding experience with allergic patients and their psychology. When one knows the allergic cause of the acute paroxysm it is easy to explain the bizarre and extraordinary circumstances under which they occur. Absolute and complete avoidance of the offending substances, whether inhalant or ingestant, is all that is necessary to bring about a clinical cure. If the substance cannot be avoided, benefit will be obtained in a certain percentage of cases by hyposensitization. If the asthma has induced incapacitating chronic pulmonary emphysema, or chronic bronchitis, or purulent sinusitis, appropriate therapeutics may be needed for these. The best prophylactic treatment is the recognition of the allergic manifestations during childhood, thereby preventing the chronically ill adult with the inevitable sequelae of frequently repeated asthmatic attacks.

In this presentation we shall limit ourselves to a discussion of the treatment of patients with allergic asthma in whom

specific treatment was of benefit. It can be readily seen that without the advantage of the knowledge gleaned from clinical observations and sensitization tests these patients undoubtedly would have had a long-standing chronic illness and that they also may have had improvement seemingly coincident with certain therapeutic measures, but actually due to the unwitting avoidance of the causative agent.

It is possible to present before you a group of patients upon whom we have information extending over many years. The knowledge of their etiologic factor makes their seemingly erratic course not surprising, and helps to explain the clinical course of other asthmatics. They make one acutely aware that in bronchial asthma, the factor of coincidence will credit many diverse therapeutic measures, either of the past or contemplated, as cures, when in reality it was the unknowing avoidance of the causative agent which initiated the cure. As an example (which appears in many different forms in one's experience with allergic individuals), there is the business man of forty-six years of age, who sought relief for his nonseasonal asthma of several years' standing, which was a recurrence of nonseasonal asthma he had had from early childhood to the age of twenty years. At that age, he came from the farm to the city and coincidentally had a nasal operation. In the course of time while living in the city his asthma disappeared. He was sensitive to horse dander, which undoubtedly accounted for his early asthma as it did for his present asthma because he had taken up horseback riding. The operation had been credited with the cure and not the unconscious avoidance of horse contact. It is interesting to speculate in those instances in our experience where the offending substance was deliberately avoided, as to what would have been credited with the cure had the same avoidance occurred unwittingly.

Case I.—The first patient I wish to present is a forty-five-year-old married woman, who was seen for the first time in 1919. At that time she was the subject of nonseasonal asthma since the age of four, and change of weather was thought to

precipitate the attacks. During her high school years she most frequently had an attack on Saturday evenings and Sundays. During the first year of her college education she had many severe paroxysms. During the ensuing vacation from college, a nasal operation was performed and the next year at college, there was improvement, attributed to the operation, in that the attacks were less frequent but no less severe. During her third year at college she again had frequent severe paroxysms. After her graduation, she spent time in various portions of the West where the attacks were also less frequent but still quite severe. In the later years of her complaint, she noticed that wheat flour produced the hay fever syndrome but was not certain that it induced the asthmatic attacks. It was in 1919 that she was found sensitive by skin tests to the proteins of wheat flour, and since that time has been free from asthmatic attacks except at those times when she has either willingly or unknowingly had contact with wheat. We are now able to explain the apparent vagaries of the disease during the early years. The asthmatic attacks on Saturdays and Sundays were due to helping with the baking, which was done on Saturdays. The Sunday asthma was due either to the tapering off of the asthma initiated by contact with wheat flour on Saturday or to the ingestion of the products baked on that day; for later observation showed that the asthma could be precipitated either by inhalation or ingestion. The severity of the first year at college was due to the fact that her course of study required the handling of wheat flour. The improvement during the second year, credited to the nasal operation, was due to not handling wheat flour during this year, the only contact being by ingestion; during the third year, flour again was handled accounting for the increase of paroxysms. She was treated by oral hyposensitization with wheat, beginning with minute quantities of wheat bread, increasing the dose every five days so that at the end of nine months, she was able to eat a satisfying quantity of wheat products. During this period and ever since, the inhalation of wheat flour has always been followed by hay fever-like symptoms and if sufficient

quantity were inhaled, by bronchospasm. In the beginning a gauze mask covering the nose and the mouth, and later a wet sponge respirator prevented these symptoms whenever handling flour.

In 1926 her thyroid was removed for hyperthyroidism. There had been no asthma. The first recurrence of frequent severe asthmatic attacks occurred in 1930 despite sedulous avoidance of contact with wheat flour, both by inhalation and ingestion. This asthma occurred in a town to which she had moved some three years previously and which contained both a flour mill and a grain elevator. She gave positive skin tests to the dust from the flour mill and from the elevator, as well as to the original wheat proteins. Moving to a town 5 miles away, containing neither a flour mill nor a grain elevator, again cured her of the asthmatic paroxysms. Had we not known of her sensitization to wheat, the elucidation of these attacks would have been a great deal more difficult. Indeed they were attributed to bacterial sensitization by the home physician. At the present time, she is free of asthma as long as she avoids inhalant contact with flour. She can again eat satisfying amounts of wheat flour products, without having had oral hyposensitization.

Case II.—The next patient is a man now forty-five years of age, who was first seen in November, 1916, at the age of twenty-five years, complaining of asthma which began at the age of sixteen years, having had a gradual onset with much coryza and cough. The attacks occurred usually in the middle of the night, and were worse in winter; the previous summer having been the first time he was troubled during the summer season. He had had the tonsils, adenoids, and turbinates removed, and the nasal septum straightened without effect upon his asthma. The past medical history had no bearing on his present trouble, except that he believed his attacks were initiated by colds, sudden chilling, drafts, or walking in the park. The physical examination showed a spare, fairly developed white male, weighing $118\frac{1}{2}$ pounds, with a

chief physical finding of expiratory musical râles diffusely scattered over his chest. The x-ray of his chest showed considerable generalized branching, dense hilus shadows on both sides extending to the bases. On November 8, 1916, he was placed upon a high caloric diet and started on injections of autogenous defibrinated blood. By January 6, 1917, he had received 8 injections of defibrinated blood in increasing doses and had gained 18 pounds in weight, but had had two severe and five light attacks of asthma. Although the gain in weight was most striking and probably beneficial and occupied the foreground of his therapeutic picture, the effect upon his asthma either of the injections of autogenous defibrinated blood, or the high caloric diet were not so striking. On this same diet he reached his best weight on March 19, 1917, weighing 145½ pounds.

He had attacks at irregular intervals averaging one attack in two weeks, some characterized as severe, others as light, until January, 1917, when they increased in severity and frequency. He received another series of defibrinated blood injections in increasing amounts, this time without specific dietary instructions. During this series, his weight decreased from 142 pounds to 124 pounds with no notable change in the frequency or severity of his attacks. Both severe and light attacks continued at about two-week intervals, and another series of defibrinated blood injections were given during 1918; again without notable influence upon his dyspnea. In 1919, he was found sensitive to wheat by the cut method.

By avoiding wheat he has remained free of asthma and the frequent so-called "colds" until August 29, 1925, when it recurred despite complete wheat avoidance. There was an associated coryza of moderate severity but no itching of the inner canthi or nose, which made pollen doubtful as the cause, and intracutaneous tests with 1:10 ragweed solution were negative. A positive intracutaneous test was obtained to corn, which elicited the information that he had been eating a great deal of popcorn. The attacks ceased when he stopped eating popcorn; but that is not the whole story. Corn meal had been

used since 1919 as a substitute for wheat flour, and he had eaten as much corn on the cob as he wanted without asthma following so that the popcorn was a specific sensitization and one assumes the other forms of corn induced no symptoms because in their preparation for the table they were exposed a longer time to heat. At least by avoiding wheat and popcorn, but eating corn in other forms, he remained free of asthma.

In 1931 he experienced a nasal infection, without asthma, necessitating irrigation of the left antrum with recovery of purulent secretion.

In early September, 1932, he again had a recurrence of asthma with coryza without itching of the inner canthi and nose. Intracutaneous tests with ragweed were negative, and positive reactions were obtained to cantaloupe, spices, chocolate, and nuts. Cantaloupe with black pepper had been eaten frequently during the previous ten days. The asthma ceased when they were omitted from the diet. He is still free of asthma by omitting from the diet wheat, popcorn, melons, chocolate and nuts.

Case III.—This patient was seen for the first time in 1921 at the age of five years, complaining of frequent colds and asthma, which he had on the average of one time a month since the age of one year. He had had eczema beginning at six weeks which lasted until about the eighth month and shortly thereafter the asthma began. He was a nursling, and the eczema disappeared when breast feedings were stopped which was coincident with the use of a new salve, which was credited with the cure but which I am inclined to believe was due to an entirely different cause. From the diagnostic standpoint, the important fact in the history of this eczema during the nursing period, was that the mother took a malt preparation to improve the quality of the milk; for skin tests were positive to wheat, egg, and potato. The asthma was completely controlled by avoidance of these foods. A fair tolerance to wheat

was obtained by oral hyposensitization and the other offending foods were gradually added to the diet.

He was seen again in 1927 because of abdominal pain which simulated appendiceal involvement. Because of the absence of the classical associated symptoms and laboratory findings, and the history of excess indulgence in wheat and egg, it was postulated that the pain was due to allergic involvement of the intestines. A subsequent attack of abdominal pain was accompanied by blue spots on the lower extremities so that the diagnosis of Henoch's purpura seemed clear. Positive reactions to wheat, egg, and potato were again obtained and when these foods were deliberately eaten, acute abdominal pain and purpuric blotches on both legs occurred within a few hours.

Another course of oral hyposensitization allowed the ingestion of adequate amounts of these foods without inducing symptoms.

Being imbued with the carefree spirit of youth, the adherence to a diet is somewhat onerous so that he has been seen from time to time since 1927 with either mild asthma or abdominal pain, always traceable to excessive indulgence in the proscribed foods. Since 1934, he has had mild hay fever like symptoms without notable itching, corresponding to the pollenating periods of the grasses and ragweed. Cutaneous reactions are positive now to the pollen of oak, timothy, and ragweed, and still to wheat, egg, and potato. Hyposensitization to these pollens has not been attempted because of the possibility of these symptoms being controlled by strict avoidance of the known offending foods, particularly so since itching of the inner canthi and nose is not present.

Case IV.—The next patient now twenty years of age was seen in the dermatologic clinic at the age of seven months in 1917, with a vesicular papular dermatitis of the cheeks which improved with medication by late spring. She was seen again in the dermatologic clinic in 1919 and 1921 with similar dermatitis, which at the last visit involved the face, arms, wrists,

elbow folds, back, and chest. Each time the dermatitis disappeared with the onset of warm weather. She was seen next in the asthma clinic in 1925, having had nonseasonal asthma with exacerbations in the spring and fall for two years. Since the advent of the asthma, there had been no dermatitis. She gave positive reactions to feathers, wool, dog, ragweed pollen, potato, and milk. She avoided contact with these and was given prophylactic injections of ragweed pollen for two seasons. There has been neither asthma nor dermatitis since 1925.

Case V.—A woman, now twenty-four years of age, was first seen at the age of ten years in 1922. At that time she had had persistent head colds with nonseasonal paroxysmal sneezing and nonseasonal asthma for two years. Most thorough rhinological operations and treatment had influenced the course of her complaint only temporarily. Positive skin tests were not obtained. She always became promptly free of her asthma with hospitalization, and it disappeared completely when she left home at the age of eighteen years, and has not recurred up to the present time. Because of the symptomatic history, the age of onset, and the prompt disappearance of asthma with each hospitalization, she was considered as having allergic asthma. Undoubtedly she was sensitive to an environmental factor, which we were unable to identify.

These patients can now experience the various circumstances, which were thought to cause their attacks. They also illustrate very well the clinical mutations of allergic individuals. Despite the clinical dissimilarities occurring during the course of their affliction, it is obvious that the treatment is the same irrespective of the phase for, or the age at which medical aid is sought. However, they are cured only in the clinical sense. Immunologically they are not cured as evidenced by the persisting cutaneous reaction, by their ability to develop new sensitizations, and by the recurrence of symptoms upon exposure to a sufficient amount of the offending agent.

The clinical experience with them warns us to beware of drawing hasty favorable conclusions from the results of therapeutic procedures. Time is the determinant of the value of therapeutic measures in allergic asthma.

The following cases illustrate some of the methods of interrogation and of treatment.

Case VI.—This young girl is now thirteen years of age and was seen for the first time in October, 1935. She had had nonseasonal asthma since the age of three years, with one week as the longest period free of her discomfort. She also sneezed excessively the year around. She was worse in damp weather. She has had no other allergic manifestations. She sleeps in a feather bed, uses feather pillows; there is a canary bird in the house; the father handles horses; she lives within two blocks of a feed store and there is a grain elevator 8 or 9 blocks away. It is thought that certain foods and odorous substances increase the severity of the asthma. There is a positive family history for allergic manifestations, in that the maternal grandfather had asthma all his life; the maternal grandmother and the mother had and have sick headaches.

When first seen she weighed 65 pounds. She was pale, had flabby muscles, and a dorsal kyphosis of moderate angulation. The lungs were hyperresonant and had lessened downward expansion. There was no wheezing. The heart was normal. Intracutaneous tests resulted only in suggestively positive reactions to all inhalants, with the larger reactions to house dust and horse dander, and to cotton seed, corn, pea, lima beans, and spices.

Fortunately, while in St. Louis, she lived with a family who practiced "allergic cleanliness,"⁴ the method necessary to avoid contact with inhalants. She became free of asthmatic attacks and, in addition, learned by example the manner in which asthmatics cooperate with their physician. She was under active observation for three weeks during which time she had one mild attack following a visit to a beauty parlor to have her hair set. Comfort was obtained by the oral use

of ephedrine 0.025 Gm. and further attacks from this source prevented by immediately thoroughly washing the hair. A high caloric, high vitamin diet was prescribed in the beginning, excluding only the foods giving suspiciously positive reactions. With the exception of cotton seed and spices, which are unimportant dietary constituents, the suspiciously reacting foods were fed deliberately. None of them induced symptoms, so that finally she ate a general diet, excluding cotton seed and spices, with special stress upon vitamin and mineral-containing foods.

At the end of our active observation she had gained 13 pounds, had better color, felt stronger and had experienced the longest period free of asthma in her life.

The skin tests are of no help in this case in identifying the specific etiologic agent, nevertheless the treatment should be along allergic lines since the clinical history and course is that of an allergic individual with allergic manifestations in her antecedents.

The clinical course points to an environmental and not a dietary factor, so that the therapy must be directed toward avoiding those present in her home environment, which were not present in the environment while living in St. Louis.

Accordingly, before she went home, the parents were sent ahead to duplicate the St. Louis environment, namely: no feathers, wool, cotton seed, house pets, orris root, and insecticides. She was instructed to avoid contact with animals, the feed store, and the grain elevator. It was explained that even under these circumstances, going home was an experimental observation. A diary was to be kept, noting all activities and all food ingested so that if the asthma recurred one knew accurately of the attending circumstances. The diet was to be similar to the one she ate while in St. Louis. Gymnastic exercises were prescribed in the hope of straightening her back. She has had no asthma up to the present time. She has not missed a day at school (and it has been a severe winter) and she weighs $87\frac{1}{2}$ pounds, a gain of 22 pounds.

The clinical experience with them warns us to beware of drawing hasty favorable conclusions from the results of therapeutic procedures. Time is the determinant of the value of therapeutic measures in allergic asthma.

The following cases illustrate some of the methods of interrogation and of treatment.

Case VI.—This young girl is now thirteen years of age and was seen for the first time in October, 1935. She had had nonseasonal asthma since the age of three years, with one week as the longest period free of her discomfort. She also sneezed excessively the year around. She was worse in damp weather. She has had no other allergic manifestations. She sleeps in a feather bed, uses feather pillows; there is a canary bird in the house; the father handles horses; she lives within two blocks of a feed store and there is a grain elevator 8 or 9 blocks away. It is thought that certain foods and odorous substances increase the severity of the asthma. There is a positive family history for allergic manifestations, in that the maternal grandfather had asthma all his life; the maternal grandmother and the mother had and have sick headaches.

When first seen she weighed 65 pounds. She was pale, had flabby muscles, and a dorsal kyphosis of moderate angulation. The lungs were hyperresonant and had lessened downward expansion. There was no wheezing. The heart was normal. Intracutaneous tests resulted only in suggestively positive reactions to all inhalants, with the larger reactions to house dust and horse dander, and to cotton seed, corn, pea, lima beans, and spices.

Fortunately, while in St. Louis, she lived with a family who practiced "allergic cleanliness,"⁴ the method necessary to avoid contact with inhalants. She became free of asthmatic attacks and, in addition, learned by example the manner in which asthmatics cooperate with their physician. She was under active observation for three weeks during which time she had one mild attack following a visit to a beauty parlor to have her hair set. Comfort was obtained by the oral use

of ephedrine 0.025 Gm. and further attacks from this source prevented by immediately thoroughly washing the hair. A high caloric, high vitamin diet was prescribed in the beginning, excluding only the foods giving suspiciously positive reactions. With the exception of cotton seed and spices, which are unimportant dietary constituents, the suspiciously reacting foods were fed deliberately. None of them induced symptoms, so that finally she ate a general diet, excluding cotton seed and spices, with special stress upon vitamin and mineral-containing foods.

At the end of our active observation she had gained 13 pounds, had better color, felt stronger and had experienced the longest period free of asthma in her life.

The skin tests are of no help in this case in identifying the specific etiologic agent, nevertheless the treatment should be along allergic lines since the clinical history and course is that of an allergic individual with allergic manifestations in her antecedents.

The clinical course points to an environmental and not a dietary factor, so that the therapy must be directed toward avoiding those present in her home environment, which were not present in the environment while living in St. Louis.

Accordingly, before she went home, the parents were sent ahead to duplicate the St. Louis environment, namely: no feathers, wool, cotton seed, house pets, orris root, and insecticides. She was instructed to avoid contact with animals, the feed store, and the grain elevator. It was explained that even under these circumstances, going home was an experimental observation. A diary was to be kept, noting all activities and all food ingested so that if the asthma recurred one knew accurately of the attending circumstances. The diet was to be similar to the one she ate while in St. Louis. Gymnastic exercises were prescribed in the hope of straightening her back. She has had no asthma up to the present time. She has not missed a day at school (and it has been a severe winter) and she weighs 87½ pounds, a gain of 22 pounds.

Case VII.—The next lad was first seen at the age of four years, in December, 1930, accompanied by overly solicitous and unduly alarmed parents (the mother reeked with the odor of orris root). At the time he had constant nonproductive cough and wheezy breathing which had been present for some eighteen hours and he reflected his parents' state of mind by extreme irritability and unmanageableness. It was impossible to obtain a coherent clinical history, and physical examination revealed no fever, dry pharynx without exudate, hyperresonant chest with diffusely distributed short inspiratory and expiratory wheezing. Control of the cough and pacification of the parents was the therapeutic goal. Accordingly, absolute bed rest and enforced quietness; 0.015 Gm. of codeine every three hours, steam inhalation, avoidance of orris root, feathers, wool, and copious fluids were prescribed. The cough and wheezing subsided within twenty-four hours, and the child was without symptoms in five days. It was now possible to ascertain that his mother, maternal grandfather, and a maternal aunt had migraine; that another maternal aunt and a maternal great-aunt had seasonal hay fever, and that the father had sinus headaches of undetermined etiology; that the patient is subject to colds, which consist of nonseasonal paroxysmal sneezing, with itching of the nose for periods of twenty-four hours; that he sneezes upon the slightest provocation; that the ingestion of chocolate is followed by vomiting; that he had a constant nonproductive cough last year and an exactly similar ailment, which resembled pertussis, the past summer; that he has had diffuse urticaria of unknown causation one time; that he has recurring perianal dermatitis, and that he had more paroxysmal sneezing the past August and September. The clinical history is that of an allergic individual.

Feathers, pyrethrum, wool, orris root, cotton seed, kapok, flaxseed, the pollen of box elder, timothy, ragweed, and marsh elder among the inhalants; radish, turnip, sardine, almond, peach, and hazelnut among the foods, gave definitely positive reactions. Suggestively positive (erythema without whealing)

reactions were obtained to wheat leucosin, bran, buckwheat, casein, coffee, string beans, and tomato, by the cut method.

As the result of these preliminary observations the parents were advised the following basic regimen: (1) Complete and sedulous avoidance of contact with pyrethrum, feathers, orris root, cotton seed, kapok, flaxseed, and wool. This necessitated a change to nonorris root containing cosmetics and powders; getting rid of overstuffed furniture, and all feather pillows; encasing the mattress with a material impervious to dust; discontinuing the use of insecticides, and the substitution of cotton for wool blankets. (2) The clinical history pointed to the recent exacerbation of nasal symptoms during August and September, so hyposensitization injections to ragweed were begun. The clinical significance of the cutaneous reactions to the pollen of box elder and timothy to be determined by the correlation of observed symptoms to their respective pollenating periods and hyposensitization injections to be instituted to these, if indicated, the following year. (3) Avoidance of the foods (including cotton seed) giving definitely positive reactions. The dietetic diary to determine the clinical significance of the foods giving suspiciously positive reactions and of foods which gave no cutaneous reaction and also to determine the unknowing use of the prohibited foods. (4) Ephedrine hydrochloride in 3 per cent solution, dose 5 to 20 drops, to control audible wheezing, and $\frac{1}{4}$ grain of codeine to control excessive cough was prescribed.

The period of observation was also utilized to impress the parents that their oversolicitude and evident alarm had a deleterious influence upon their child. Children with asthma should lead a normal existence, should indulge in the ordinary and usual activities of children. The only restrictions placed upon them relative to their affliction, should be the absolute prohibition of those substances proved by clinical trial to induce their attacks. As a matter of fact, when children learn that certain substances induce their asthma, they are more cooperative than adults.

During the subsequent years he was observed with small

amounts of dermatitis in the elbow and knee folds which appeared to follow the ingestion of orange juice. Chocolate, egg, chicken, and wheat induced vasomotor rhinitis. The most severe attack of asthma under observation developed in 1932, the first night he slept on a newly purchased day bed, which was said to contain no cotton seed because the label stated it was made from "pure cotton linters." An exactly similar episode occurred a year later while visiting in another city.

Transient and mild nasal symptoms developed during the pollenating periods of box elder and timothy. He was given prophylactic hyposensitization injections to ragweed for three sequential years. The first year he had moderately severe nasal symptoms without asthma. These were alleviated by avoiding chocolate, chicken, egg, and wheat in the diet and staying indoors in a closed room during periods of greater severity. The second and third years, he had only occasional nasal symptoms, not requiring pollen precautions, by avoiding the same foods. No ragweed hyposensitization injections have been given since 1933. There has been no asthma but he still avoids the inhalant allergen. The previously implicated foods are only strictly avoided during the ragweed season, during which time he has no more than a wet nose. As yet no symptoms are present during the period of timothy or box elder pollination.

He has grown and developed satisfactorily and his back is straight. As you will recall the previous case had a kyphosis as the result of constant asthma beginning about the same age as in this boy. He had the potentiality of developing the same deformity. The clinical course points to cotton seed as the dominant cause of his allergic asthma.

Although it is unusual for allergy to induce active symptomatology in those of advanced years, nevertheless by applying the criteria for its recognition to those past the fifth decade, one may identify some of these senescent complaints as being allergic in nature. The following two cases are examples of allergic asthma in those of advanced years.

Case VIII.—This woman was seen for the first time in early 1934, at the age of sixty-one years. She complained of sneezing, coryza, and cough leading to chest oppression with wheezy breathing of such severity as to require epinephrine for relief since November, 1933. Six years previously she had had similar chest oppression, often with head colds, for a period of two years. She also has, for the past several years, dyspnea without wheezy breathing upon moderate exertion.

Up to six years ago she had been in excellent health, living and working upon a farm as well as rearing ten children. There have been no physical ailments suggestive of hypersensitiveness up to that time. Since, hives occurred one time following a hypodermic injection to relieve an asthmatic attack; another time she has had edema of the lips and cheeks suggestive of angio-edema; during the past two winters, she has had frequent and nearly continuous head colds characterized by nonpurulent nasal discharge, intranasal blocking and without fever; aspirin is followed by a burning sensation in the epigastrium and a smothering feeling but never a definite asthmatic seizure. No history can be elicited of allergic manifestations in her antecedents.

The onset of her presumed allergic symptoms is not concurrent with any change in her environment. Feather pillows and wool comforts are used for bedding, and cattle, chickens, and cats are close by her house.

Essentially, on physical examination, are mildly cyanotic lips, a heart rate of 100 beats per minute, the second aortic and pulmonic sounds are of equal intensity, no wheezing breath sounds, three fingerbreadths and two fingerbreadths downward expansion of the right and of the left lung respectively; blood pressure, 140/90; fixed kyphoscoliosis, and uniformly thickened brachial arteries. A moderate number of eosinophils were found in the sputum.

The immediate therapeutic need was to lessen the cough, which was accomplished with codeine. Definitely positive reactions to the pollen of oak and ragweed were obtained by the intracutaneous method. The remainder of the inhalants

while not giving unmistakably positive reactions always produced larger intracutaneous responses than the foods, with the exception of spinach, turnip, lettuce, asparagus, corn, beans, cantaloupe, cabbage, and sweet potato. Accordingly she was advised to get rid of all the feathers in the house, the wool comfort, to stay out of the chicken house and the barn.

With adherence to these instructions, within a month there was lessening of the frequency and intensity of the chest oppression. Since that time she has had no dyspnea. During the latter part of August, there was a mild vasomotor rhinitis, probably due to the pollen of ragweed. It required no specific treatment. No symptoms developed during the period of oak pollination. Hyposensitization to these pollen is not indicated until symptoms of incapacitating intensity develop when these pollen are in the air.

Case IX.—This patient was seen for the first time in 1926, at the age of sixty-eight years, complaining of nonseasonal asthma over a period of thirty-five years. She had frequent head colds (afebrile, stuffiness in the nose with nonpurulent discharge) during the winter and was an easy sneezer at all times. There was no distinct seasonal variation of the intensity or frequency of the sneezing. She had been in excellent health otherwise. She had had no other allergic manifestations nor were there such in her antecedents.

The essential points in the physical examination were a moderate pulmonary emphysema and overweight. Both the sputum and the nasal secretion contained many eosinophils. Intracutaneous tests were positive to feathers, orris root, wool, and horse dander in equal intensity among the inhalants; and tomato, potato, black pepper, and string beans among the foods.

She remained under observation two months without notable improvement because, as later observation showed, she was not convinced that her "nice feathers" which had been in the family for two generations "could give her asthma."

She was next seen in early 1935 at the age of seventy-

seven years, because she was no longer obtaining relief from the patent nasal spray and patent medicines. The physical examination revealed short inspiratory and expiratory wheezing diffusely distributed over the chest cage in the sitting posture, no downward expansion of the lungs, and moderate cyanosis of the lips and nail beds. The recumbent posture quickly intensified her discomfort and the sitting posture was made more comfortable by many large feather pillows. She was placed in the hospital where she completely avoided feathers, wool, and orris root, and foods eliminated from her diet as indicated either by intracutaneous tests or the dietetic diary. She became free of asthma in seven days. At this observation, she gave intracutaneous reactions to milk, pepper, tea, banana, and spices among the foods, and feathers, wool, pyrethrum, and orris root among the inhalants.

This experience was sufficiently impressive so that she willingly duplicated the hospital environment in her home. As the result, she now has been free of asthma and head colds for a longer period than any time during the past forty-six years. The foods giving positive reactions have been added without inducing any symptoms so that the "nice feathers" probably were the dominant cause of her discomfort.

SUMMARY

Epinephrine, hypodermically, is the sole drug to be used to relieve the acute asthmatic paroxysm. In one unaccustomed to its use, 0.3 cc. is usually sufficient. When the attack is continuous, sedation is necessary and often life-saving, especially when extreme pulmonary dilatation exists. Oxygen is helpful when more than a mild degree of cyanosis exists. The oral use of ephedrine is efficient only for mild attacks. The prolonged or continuous attack is often benefited by change to an environment where all the usual offending allergen are absent. Occasionally such attacks are also mitigated by a short period of starvation or by elimination diets. During all attacks the patient should be kept in a warm room and bodily warmth maintained.

Paroxysms of bronchial asthma are prevented by completely avoiding contact with the offending substance and all other factors which act as secondary stimuli. The principal reason for therapeutic failure is the superficial and incomplete instructions to the patient as to the manner in which he obtains contact with offending substance and the means he must employ to rid himself of that contact.

Hyposensitization should be employed when it is impossible to avoid the offending allergens. For the foods, this is best accomplished by the oral route, beginning with infinitesimal amounts and increasing the dose until normal amounts can be taken. For the inhalants, the method is identical with the methods used for the treatment of hay fever with pollen solutions.

The best therapeutic results in bronchial asthma are obtained by: a study of the patient as a whole, considering his heredity, his environment, and his peculiarities; correcting the abnormalities found by physical and laboratory examinations; evaluating the influence of controlled environments; interpreting the observed reactions resulting from cutaneous testing, ingestion of foods, and administration of drugs in the light of past experiences, and the application of treatment guided by the integration of this knowledge.

CLINIC OF DR. ALEXIS F. HARTMANN

FROM THE DEPARTMENT OF PEDIATRICS, WASHINGTON UNIVERSITY SCHOOL OF MEDICINE AND THE ST. LOUIS CHILDREN'S HOSPITAL

VOMITING IN THE NEWBORN

THE occurrence of vomiting in the newborn or young infant demands prompt investigation. While it may prove of little significance in a majority of cases, neglect of it in others may lead to serious results in a number of ways: (1) aspiration into the lower respiratory tract may result in asphyxia or fatal infection; (2) the *causative* factor may escape early detection and progress to a degree dangerous to life; or, (3) the resultant intake of food and water may be so reduced as to lead to severe degrees of malnutrition, dehydration, and chemical changes in the body fluids.

The most frequent causes for vomiting in the young infant may be classified for purposes of discussion as follows:

- I. Improper food or technic of feeding:
 - (A) Too much swallowed air.
 - (B) Too much food.
 - (C) Too frequent feedings.
 - (D) Unsuitable composition of food.
- II. Obstruction in the gastro-intestinal tract:
 - (A) Esophageal.
 - (B) Pyloric.
 - (C) Duodenal.
 - (D) Anal.
- III. Infection:
 - (A) Enteral.
 - (B) Parenteral.
- IV. Derangement of central nervous system:
 - (A) Intracranial conditions.
 - (B) "Autonomic imbalance."
 - (C) Habit.

I. IMPROPER FOOD OR TECHNIC OF FEEDING

(A) **Too Much Swallowed Air.**—Air seems always to be swallowed during the act of nursing. Undoubtedly, however, some infants tend to swallow much more air than others, and these may be either breast-fed or bottle-fed infants. Inverted or poorly developed nipples and an insufficient milk supply seem to be the chief reasons for swallowing too much air in the case of the breast-fed infant. In the case of the bottle-fed infant, nursing in the supine position, especially when nipples with improper-sized holes are used, usually accounts for the difficulty in the bottle-fed baby. Improvement usually follows correction of these factors, particularly if the infant is made to belch once or twice during the feeding and again at its end. Belching, of course, should be done in the upright position. It is surprising, however, how difficult it is to hold a very young infant properly on one's shoulder when he insists on keeping his thighs sharply flexed on his abdomen, but in other respects acts more like a jellyfish. In such infants more favorable results may frequently be obtained by holding him in the sitting position on one's lap, or balancing him, face downward with his abdomen on the palm of one's hand.

(B) **Too Much Food.**—Vomiting following the ingestion of too much food is more likely to be seen in the bottle-fed than the breast-fed infant, because of the fact that too dilute formulae are apt to be offered the former, necessitating a large volume to provide adequate caloric intake. When the caloric value of the feeding averages about 20 calories per ounce (as is true of normal human milk) it is unusual to see healthy infants incapable of taking and retaining sufficient quantities to meet their caloric needs. This happens fairly commonly, however, in premature babies, and somewhat less frequently in undersized infants, especially when handicapped by serious constitutional abnormalities.

(C) **Too Frequent Feedings.**—Vomiting of some degree,

which may be no more than a small amount of "regurgitation," is, as a rule, seen in infants fed irregularly and oftener than every three hours. The reason apparently is that the stomach has not been given time to empty itself completely before more food is offered, and satisfactory results usually follow the lengthening of the feeding interval to four hours.

(D) **Unsuitable Composition of Food.**—In addition to food that has been contaminated by bacterial toxins or by the products formed from the milk itself by bacterial growth, other factors, both physical and chemical, may make milk so unsuitable to the newly born infant that vomiting is provoked: one is the large tough curd that forms in the stomach when raw cow's milk is fed. When undiluted cow's milk is fed, many babies seem to have a delayed gastric emptying time, due to the high alkaline buffer content of such milk. When milk mixtures particularly high in fat are used, delayed emptying of the stomach also tends to occur, and provokes vomiting. Milk itself, or one of the addition products, may also act as a specific allergen in the sensitized infant, provoking vomiting.

II. OBSTRUCTION IN THE GASTRO-INTESTINAL TRACT

(A) **Esophageal Obstruction.**—In the newly born infant in whom the first attempt to offer water is followed by prompt vomiting or associated with apparent difficulty in swallowing, one should suspect at once esophageal obstruction. In such infants food or water are usually vomited unchanged, and a diagnosis can promptly and accurately be made by the use of opaque feedings and fluoroscopy or x-ray. Even though this condition is recognized immediately and a gastrostomy is made, and the infant fed by this route, he is unlikely to live any length of time because of the fact that, in addition to the atresia of the esophagus, there is usually a tracheo-esophageal fistula below the obstruction. Gastric juice with or without food may at any time be regurgitated

up into the esophagus and spilled into the trachea through the fistulous opening, and lead to fatal pulmonary changes.

In addition to congenital atresia, partial esophageal obstruction may also occur by compression from an enlarged thymus or heart.

(B) **Pyloric Obstruction.**—Contrary to the frequently made statement that vomiting in cases of congenital hypertrophic pyloric stenosis does not begin until about the third week of life, we note that not infrequently this symptom is

Fig. 38.—Incidence of onset of symptoms of pyloric stenosis by age in weeks.

fairly common even in the first week. From Fig. 38 it can be seen that in about 17 per cent of the cases observed at the St. Louis Children's Hospital during the period of 1916 to 1932 vomiting began during the first week of life, about 21 per cent in the second, and 23 per cent in the third. Cases subsequently admitted show the following incidence of onset: 16 per cent in the first week, 43 per cent in the second, and 20 per cent in the third. It is true, however, that the earliest vomiting in cases of pyloric stenosis is not usually as severe as it tends to become later. In this condition the vomitus is

characteristically unbile* stained, strongly acid, and vomiting may occur at any time in relation to the feeding, and as it increases in frequency tends also to increase in amount and become projectile. This condition is usually quite readily diagnosed when one notes in addition to the above symptoms, the presence of exaggerated gastric peristaltic waves, whether or not the hypertrophied pyloric musculature (tumor) can be palpated; likewise a barium milk feeding usually gives characteristic fluoroscopic or x-ray findings, in that there is usually little or no initial clearance into the duodenum of the material, and a very greatly delayed emptying of the stomach, so that from four to six hours after a feeding almost the entire amount may still be present in the stomach.

Successful treatment of pyloric stenosis depends not only on the type of treatment used, but also on the early recognition of this trouble, and on the proper preoperative preparation and postoperative care. As may be noted from Fig. 39, the percentage of patients treated surgically increased steadily from 1916 to 1929, so that since the latter date practically all the patients admitted to the St. Louis Children's Hospital have been operated upon. The mortality varied inversely with the percentage of patients treated surgically. The operative procedure has been that of Fredet-Rammstedt, and has been described in detail by Clopton and Hartmann.¹

Preoperative Preparations.—Satisfactory preparation for operation must include: (1) relief of dehydration and alkalosis, (2) at least partial restoration of glycogen reserves, (3) restoration of diminished plasma protein content and red blood

* Since regurgitation of the duodenal secretions into the stomach is a physiological phenomenon, and since during the earlier stages of pyloric stenosis unquestionably considerable patency of the pylorus exists, it is indeed strange that such a remarkable lack of bile in the vomitus in this condition seems to occur. Recently we have noted associated "coffee grounds" vomitus and tarry stools in an infant who at operation was found to have pyloric stenosis, and in whom a Fredet-Rammstedt operation was followed by complete correction of the condition. There was a question, however, of the presence of a gastric ulcer adjacent to the upper edge of the pyloric musculature which had an unusually sharp edge.

cell volume, and (4) control of infection. Ringer's or lactate-Ringer's solution should be administered subcutaneously or intraperitoneally to relieve dehydration and alkalosis, dextrose to abolish ketosis and restore glycogen reserves (a 10 per cent solution given intravenously), and citrated whole blood (intravenously) to restore plasma protein and red blood cells.

Fig. 39.—Percentage of patients with pyloric stenosis operated upon by year, and percentage of mortality in pyloric stenosis by year.

As often as not, otitis media will be present, and requires myringotomy and nasal treatment to control the infection.

Postoperative Care.—Experience has gradually taught us how best to take care of such infants after a successful operation. One of the most important points concerns the manner of feeding. The routine at the St. Louis Children's Hospital at present is as follows: two hours after operation $\frac{1}{2}$ ounce

of sterile water or 10 per cent buffer water* is offered, and two hours later $\frac{1}{2}$ ounce of a formula. (If the baby has been breast fed and breast milk is available, it should be used instead.) The formula consists of equal parts of evaporated milk, 20 per cent buffer water and sterile water to which is added enough carbohydrate in the form of Karo syrup to provide a final addition of 4 to 5 per cent. For the first twenty-four hours the formula and water administration are continued alternately every four hours, the volume of each being kept at $\frac{1}{2}$ ounce. During the next twenty-four hours the quantity of each is raised to 1 ounce, during the third day to $1\frac{1}{2}$ ounces, etc. After about one week the buffer solution can be discontinued and the usual 1 per cent lactic acid diluent substituted. Also, the formula may be made more concentrated by omitting all or part of the sterile water. It has been our experience that this type of feeding accomplishes two purposes: (1) the increase is slow enough to make postoperative vomiting extremely rare, and (2) the addition of the buffered lactic acid apparently is very effective in preventing the Zed reaction of Zahorsky.² It is our belief that this postoperative phenomenon is due to the presence and growth of *Bacillus coli* high in the small intestinal tract, which are permitted to multiply rapidly as soon as the pylorus is made patent by the operation, and in that respect it is very much like the more common type of nonspecific diarrhea seen in young babies during hot weather, or associated with parenteral infection.³

(C) **Duodenal Obstruction.**—Occasionally an infant is born with atresia of the duodenum. This is usually below the common duct, and gives rise quite early to vomiting. Vomiting is likely to be projectile, but bile-tinged. Just as in pyloric stenosis visible gastric peristaltic waves may be seen.

* Concentrated buffer solution has the following composition:

U.S.P. lactic acid (75-85 per cent)	150 cc.
10 per cent sodium hydroxide	200 cc.
Water to make	1000 cc.

By 10 per cent buffer water is meant a 1:10 dilution of this concentrated solution.

Stools continue to be meconial, and may be entirely uncolored. When duodenal obstruction exists as the only congenital malformation of the gastro-intestinal tract, and is not accompanied by atresia elsewhere, its prompt recognition becomes important, since operative correction by gastrojejunostomy usually leads to excellent results. Not infrequently the lesion is not that of complete atresia, but just narrowing, and occasionally congenital bands may produce duodenal obstruction. Much the same symptoms may result, and treatment also requires surgical correction. The preoperative preparation and the postoperative management are identical with that for pyloric stenosis outlined above.

(D) **Anal Obstruction.**—Imperforate anus may be present at birth and eventually lead to abdominal distention and vomiting. Vomiting comes on rather late, however, in this condition, which should never be undiagnosed since a careful examination makes its presence readily discernible. The correction, of course, is surgical. Occasionally the anal obstruction is just a narrowing of the lumen of the bowel at or just above the internal sphincter. In such instances digital or instrumental dilatation, frequently repeated, may prove effective in relieving the obstruction.

III. INFECTION

(A) **Enteric.**—Enteric infections are very rare in the newly born breast-fed baby for obvious reasons. In bottle-fed babies, however, despite the usual precautions taken, the intestinal tract is soon invaded by the colon bacillus group. Not infrequently on the third or fourth day after birth there is distinct fever with some vomiting and frequent bowel movements, which coincides with the infestation of the bowel by *Bacillus coli*. Other organisms, however, such as the members of the typhoid dysentery family, are more prone to lead to digestive upsets, characterized by vomiting and diarrhea. Such infections, however, are very rare in the newborn.

(B) **Parenteral.**—Almost any parenteral infection of a degree sufficient to produce fever may be accompanied by vomiting in the newborn or young infant. This is particularly true of upper respiratory tract infections, and especially when there is otitis media. The exact cause for this is not thoroughly understood, and probably depends upon at least three factors: (1) nasal obstruction accompanying the rhinitis, which interferes with nursing and probably leads to considerable swallowing of air, (2) swallowing of organisms draining down from the nose, and (3) absorption of bacterial toxins.

Second only to respiratory tract infections in producing vomiting is infection of the urinary tract. It is not uncommon to note evidence of pylorospasm during acute pyelitis, and vomiting may be quite projectile. In addition to pylorospasm, frequently abdominal distention develops, which may further increase the tendency toward vomiting. Omphalitis with involvement of the peritoneum likewise is not an infrequent cause for vomiting in the newborn.

IV. DERANGEMENT OF CENTRAL NERVOUS SYSTEM

(A) **Intracranial Conditions.**—Birth trauma with hemorrhage giving rise to increased intracranial pressure usually is associated with vomiting. So likewise is meningitis. In such cases vomiting occurs at any time in relation to food intake, and apparently is not accompanied by nausea, and is not likely to be associated with diarrhea.

(B) **"Autonomic Imbalance."**—Not infrequently one meets young infants who tend to be hypertonic and show evidence of gastro-enterospasm. This subject has received considerable attention in pediatric literature, and is reviewed in this number by P. J. White. The condition is looked upon as due to autonomic imbalance, and as part of the pylorospasm, vomiting may be a common occurrence. This condition can usually be distinguished fairly easily from real hypertrophic pyloric stenosis in that frequent stools rather than constipation are the rule, and the vomiting is usually re-

lieved fairly completely by the use of sedatives and drugs capable of relaxing smooth muscle spasm, such as phenobarbital and atropine.

(C) **Habit.**—Occasionally in young infants, but not in newly born ones, one may see habit vomiting fairly well developed. Shortly after a feeding the infant may be noticed to move its jaws, ruminate, and finally vomit. It gives the appearance of vomiting deliberately. Treatment may be at times difficult for this type of vomiting, and thick feedings which make vomiting more difficult are often of assistance, together with mechanical devices that may prevent jaw motion. The maintenance of the erect or semi-erect position after feeding, and the free use of sedatives are also indicated.

CONTRIBUTION BY DR. ISAAC Y. OLCHE

FROM THE DEPARTMENT OF SURGERY, UNIVERSITY OF
SOUTHERN CALIFORNIA

THE DIFFERENTIAL DIAGNOSIS OF DISEASES OF THE BREAST

THE differential diagnosis of diseases of the breast concerns itself with the separation of the inflammatory from the neoplastic processes and the further division of the latter into benign and malignant classifications. In a group by itself is the condition usually referred to as chronic cystic mastitis and its recognition in its various forms and its relation to carcinoma adds considerably to the difficulty in diagnosis of breast conditions. The various diseases, themselves, remain the same as in the past; but our conceptions of the etiologic factors are changing, due largely to a better understanding of the intimate relationships between a certain group of hormones and the breast. This is especially true of chronic cystic mastitis and the tumors, but does not obtain in inflammations of the organ.

In dealing with a patient presenting herself with the complaint of some disorder of her breast, a careful history is the first essential point. This should go back as far as the patient can recall any unusual changes in her breast. The feeling is that breast symptoms are intimately bound up with the menstrual history, so that the onset of menses, their regularity and duration, should be noted and whether or not there has been any pain in, or enlargement of, the breasts either immediately preceding menses, or during the intermenstrual interval, or at a time corresponding to ovulation. The number

of pregnancies should be noted, whether or not these terminated in normal deliveries, and if so whether or not the child, or children, was nursed and for how long. If a pregnancy terminated in a miscarriage or abortion it is important to know at what month and whether there were any complications, such as pelvic inflammatory disease which quite often follows an induced abortion. The presence of other pelvic disease should be ascertained, such as tumors or cysts, which the patient may know she has or for which she may have previously been operated upon.

The next step is the examination of the patient and in addition to the usual complete physical examination, special attention, of course, is paid to the breasts and the pelvis. For the breasts the patient is first examined in a room with good light, preferably from a window, and is seated facing the source of light. The points noted are the size of the breasts, of the nipples, and their relative position, also whether or not a tumor mass can be seen. This is further determined by palpation which enables us to decide whether there is a definite tumor present and if so, its consistency, its mobility, and whether it is separate and distinct from the rest of the breast parenchyma or intimately fused with it. The consistency of the rest of the suspected breast tissue and of the opposite breast is also noted. Axillary lymph nodes are best palpated with the patient in a sitting position. The arm is abducted and the examiner's hand is inserted as high as possible into the axilla. The palm of his hand faces medially and presses against the chest wall. This means that the right hand of the examiner explores the left axilla of the patient and vice versa. With the hand high in the axilla, the patient's arm is now brought back as close as possible to the chest wall and the palpating hand is brought down out of the axilla. Any existing axillary nodes are now felt between the hand and the chest wall. The patient next lies down and the examination of breast and axilla is repeated, making additional note of flattening out of the skin over the tumor and the presence of supraclavicular nodes.

Whenever possible, a pelvic examination should be made as it is an important part in the examination of every patient with a breast tumor, particularly if the presence or nature of the latter is questionable. If a definite tumor is present the presence of pelvic disease will not alter any proposed operative procedure, but the added information may change the postoperative course of treatment or such information may be of value in the future care of the patient. The above remarks concern themselves mostly with tumors; the possible relationship of these to pelvic disease and hormone influence will be discussed later.

INFLAMMATORY DISEASES OF THE BREAST

The etiologic factors in the true inflammations of the breast are not as obscure as with the neoplasms. As usual, we classify inflammations as acute and chronic, the former being more frequently encountered.

Acute Pyogenic Mastitis.—This is the type usually referred to as breast abscess or pyogenic mastitis because of its intensity and the organism or organisms causing it. It most often is associated with lactation and is probably a quite common occurrence. Its exact frequency cannot be determined because many of these patients are treated at home or at their doctor's offices and only a relatively small percentage of the cases find their way to the clinics or hospital wards. Because of its association with lactation, acute pyogenic mastitis is a disease of younger women, of those in the childbearing period of life. Instances before puberty and after the menopause are very uncommon and when they do occur are more apt to be infections or abscesses of the adjacent tissues which secondarily involve the breast. These, of course, are not associated with lactation and one also occasionally encounters true breast abscesses in younger women who are not lactating. Such infections we assume to be hematogenous in origin; and where there is a history of trauma preceding the infection, then the further assumption is that the hematoma

or traumatized tissue acted as an area of decreased tissue resistance (*locus resistencia minoris*); and the bacteria, lodging there from the blood stream, found local conditions more favorable for their growth. In the usual case of pyogenic mastitis associated with lactation, the bacteria enter the breast by growth along the lymphatics which follow the excretory ducts. These lymphatics are much more prominent and patent during lactation than in the resting breast, and the bacteria enter them through cracks or fissures in the skin of the areola and nipple. What begins as a lymphangitis rapidly extends into the very cellular hyperplastic parenchyma. The invading organism usually is the *Staphylococcus*, either alone or with some other micro-organism. Infections due to other bacteria alone, such as *Streptococcus*, *Pneumococcus*, *Bacillus typhosus*, have been described but are uncommon.

There is no proof that the bacteria cannot enter the breast by traveling up the lactiferous ducts, but if this does happen it must be in ducts filled with stagnant secretion; otherwise the flow of the secretion would carry the organisms down before they could gain access to the substance of the breast. Our feeling is that the bacteria enter the periductal lymphatics through cracks, fissures or abrasions on the nipple or areola, giving rise to an acute lymphangitis. The organisms then very quickly find their way into the breast parenchyma, which is now very cellular as it is composed predominantly during lactation of glandular epithelium. This tissue is not resistant to infection and very easily undergoes disintegration and liquefaction, giving rise to one or more abscesses. Several of the latter may fuse into one large abscess. From such a mode of origin one understands how one breast alone may be involved and how the infection may be limited to only a portion of that breast. Bilateral acute pyogenic mastitis does occur, but not very frequently, and the infection may be simultaneous or one abscess may follow its predecessor by an interval of several months during the same period of lactation. Recurrent infections in different periods of lactation may also occur and an individual is just as liable to the in-

fection during one lactation as during another. The general feeling, however, is that more abscesses occur following the first pregnancy, and this is supposed to be due to the fact that the thin skin covering the nipple and areola is not as resistant in the beginning of the first period of lactation as later. The gross and microscopic picture of a breast abscess is that of an acute pyogenic infection anywhere else on or immediately beneath the body surface and the pathology of such an abscess need not be discussed here.

The differential diagnosis of the usual acute pyogenic mastitis should present no difficulties. The patient is a young woman who has not gone far into her period of lactation. The affected breast is wholly or partly reddened, tender, larger than the opposite one, shows increased local heat; in short, all the cardinal signs of an acute localized infection. There is enlargement and tenderness of the regional axillary lymph nodes and these may break down and form secondary abscesses. Because of the induration, the breast is firmer than the unaffected one and the nipple is at a relatively higher level. The patient has some degree of fever and there should be a leukocytosis with an increased proportion of polymorphonuclears. The difficulty in diagnosis is found in those abscesses not associated with lactation, or in those cases not accompanied by the usual general and local manifestations of an acute infection. A patient recently seen illustrating the latter was a thirty-nine-year-old multipara, delivered of a normal child a month previously. Following this delivery she noticed that her left breast was hard and larger than the right. There had been no increase in size during this month and there was no pain, local heat or tenderness. The breast parenchyma did not transilluminate as the adjacent fatty portion of the breast did. The temperature was normal. The impression up to this point was that of carcinoma in a lactating breast. Aspiration biopsy was then done and pus only was recovered. Accordingly, incision and drainage of the breast was carried out. No explanation can be offered why the abscess occurring in this lactating breast should not have

given the train of acute symptoms and findings usually seen in such cases. When occurring in a nonlactating breast an abscess may simulate a solid tumor in that the pus may be under such tension and so covered with subcutaneous and breast fat that fluctuation cannot be elicited. We have seen such abscesses where also the mass made its appearance some weeks or more previous to the first examination and had grown slowly during the interval and without the local or general accompaniments of an abscess. In our experience these few cases have been mistaken for large solid tumors such as fibro-adenomas. Although the temperature may be normal, there will be a leukocytosis and an aspiration biopsy will reveal the true nature of the lesion and indicate the subsequent treatment.

Chronic pyogenic mastitis may occur but where found it is considered a sequela of a previous abscess. The acute mastitis involving a lactating breast usually disappears following incision and drainage. This rapid healing may be aided by the involution occurring in such a breast, inasmuch as the mother is not allowed to, or cannot nurse at the involved breast. Sometimes this rapid healing does not take place, especially where the abscess is involved in a nonlactating breast, and the sinus or sinuses following drainage may persist. This is due to the failure of collapse of the abscess cavity and to the fact that it contains active infected granulation tissue, which keeps up the discharge.

Tuberculous Mastitis.—The other chronic inflammatory process involving the breast with any degree of frequency is tuberculosis. Since this disease was first described in the breast by Sir Astley Cooper in 1829, about 500 cases have been reported, not a great number when compared with the incidence of pyogenic mastitis, carcinoma of the breast, or tuberculosis elsewhere in the body. Roughly, about 1 per cent of breast tumors are said to be due to tuberculous mastitis. A few of these cases have been reported in males, but by far the most of them have been in younger women, most frequently married women who have borne children. In other words,

the marked changes in the breast incident to hyperplasia and regression may be predisposing factors. The infection is, of course, due to the tubercle bacillus which has been demonstrated in and isolated from the lesions. In a few instances the strain of bacteria was identified and the bovine found each time (Barker). This series is, however, too small to be taken as final.

The mode of entrance of the organism into the breast is also a subject of some dispute. The majority of writers feel that the infection is hematogenous, although there is no proof of this and no explanation can be given for the lodging of the bacteria in the breast. There are others who feel that the infection is by retrograde lymphatic extension, pointing to the frequency with which tuberculous axillary lymphadenitis has preceded the lesion in the breast. The third possible mode of entrance is by duct extension into the breast from a tuberculous infection in an immediately adjacent tissue, such as a tuberculous empyema or osteomyelitis. Another possibility is direct infection of the breast through an abrasion or crack in the skin of the nipple or areola. The disease is commonly divided into the primary and secondary forms. In the primary, it is limited to the breast and no tuberculosis can be demonstrated elsewhere in the body, nor has there been a history of previous infection. The opposite is the case with the secondary form. In various reported series, the primary cases are found about twice as frequently as the secondary ones. Many, however, maintain that all are secondary to infection in another part of the body which cannot be demonstrated at the time; in which respect the disease resembles tuberculosis of the kidney.

Tuberculous mastitis is usually unilateral. Deaver has described several forms of the process and these depend on the rapidity of progress of the disease, the amount of necrosis, abscess formation and fibrosis. In the nodular form one or more discrete tubercles arise in the connective tissue accompanied by marked lymphocytic infiltration which soon destroys the acini. The tubercles break down, undergo liquefaction

and the resultant abscess fuses with other adjacent ones and with the space formerly occupied by the acini, and one large or several smaller abscesses arise. There is some degree of fibrosis around all of this so that a hard mass is felt on palpation. Such an abscess may increase in size and eventually burrow through the skin to evacuate itself and leave a permanent sinus. In most instances the axillary glands are involved and enlarged. These also may break down to give rise to sinuses and cases are recorded where the axillary infection was noted before that in the breast. The other gross form of the disease is the sclerosing type. This is merely a slower, more indolent form in which fibrous tissue proliferation predominates and little or no caseation and necrosis occurs. These forms are not very distinct and often cannot be separated.

The diagnosis of tuberculous mastitis, as usually seen, often presents difficulties because of its resemblance to other conditions. If there is active tuberculosis elsewhere in the body, or a previous history of it in a woman with a slowly progressing, usually painless lump in the breast, tuberculosis should be considered. If enlarged axillary nodes were noted first and then the lump in the breast, again tuberculosis should be thought of. Where a definite abscess can be made out, or the latter has broken through the skin leaving a persisting sinus, the diagnosis may be easy. The abscess may be aspirated and the material obtained examined for bacteria, cultured and a guinea-pig inoculation done. The sinuses may be carefully curetted and the bits of tissue obtained submitted for microscopic section. However, we do not always have the abscess or the sinus or the preceding axillary adenitis or active tuberculosis elsewhere and so we may have only a patient with a lump in the breast, which may have been noticed several months, with no definite history or symptoms to aid in establishing a diagnosis. Such a mass is usually painless, not associated with secretion from the nipple and because of the sclerosis around the process the deeper layers of the skin may seem to be attached to it. The diagnosis then is made by exclusion and the differentiation from carcinoma is not an

easy one. Age of the patient is not an important point unless the individual is quite young, as many instances of both diseases are found in the thirties and over. The history and findings may be the same in both instances. A patient with previous or present tuberculosis may also develop cancer of the breast and we have seen cases of the latter disease where the axillary metastasis was noted before the primary tumor. The two conditions have also been described in the same breast. Transillumination of the breast may give no definite information. The next step should be an aspiration biopsy and if this should prove inconclusive then exploration of the breast with wide excision of the tumor area or even of the whole breast parenchyma for immediate examination should be carried out. In the final analysis, then, the diagnosis can be made only by direct gross and microscopic examination of the tissue. In the course of such a diagnostic procedure other neoplasms of the breast will be ruled out.

Pyogenic mastitis, acute or chronic, is differentiated by the history, local findings, leukocyte count, if acute, and finally by aspiration biopsy. The other chronic inflammatory diseases of the breast, such as lues, actinomycosis, etc., are so uncommon that they need not be discussed at this time.

TUMORS OF THE BREAST

The classification of tumors of the breast is now a very simple one. The cysts or cystic tumors are now considered variations of chronic cystic mastitis. The solid tumors are divided into the benign and the malignant and of these the former will be considered first.

Fibro-adenoma.—These are the simple fibro-adenomas and the intracanalicular fibro-adenomas. They are tumors found nearly always in women and make their appearance only after puberty. They may be found after the menopause, but this is very uncommon, the feeling being that in such cases the tumor began its growth before the menopause and was perhaps unnoticed until afterward. The simple fibro-aden-

omas tend to appear within a few years after puberty while the majority of the intracanalicular type are found later on, usually after the age of twenty-five. There may be no sharp distinction between the tumors, and a simple fibro-adenoma quite often has areas of intracanalicular change in it. The writer feels that the simple fibro-adenoma, if left alone, will later become an intracanalicular one. The frequency of these is difficult to determine. In the Laboratory of Surgical Pathology of Washington University, their incidence was about equal to that of carcinoma of the breast and both the simple fibro-adenoma and the intracanalicular one occurred with about equal frequency. This may or may not be the experience in other clinics, but the general opinion is that these solid benign tumors are being seen more frequently than they were twenty-five or more years ago. The reason for this is largely due to the dissemination to the lay public of information concerning cancer. With the general realization that early cancer of the breast can be cured, more women are seeking medical advice much sooner after first noticing a lump in their breasts. This means that breast lesions are being seen earlier in their course and more of the benign tumors are encountered.

The cause of the growth is known in part. According to Cheate, the simple fibro-adenoma is the result of the localized proliferation of the pericanalicular connective tissue. In his studies he has identified the fine layer of elastic tissue that surrounds the ducts and even some alveoli. Immediately outside this layer is the peculiar cellular connective tissue intimately associated with the ducts. This connective tissue is not the same as the interlobar connective tissue which acts as the general supporting framework of the whole gland. In response to some stimulus, so far not definitely known, this pericanalicular or periductal connective tissue undergoes proliferation which remains localized and, hence, the whole mass is encapsulated. Similarly there is another layer of this same connective tissue immediately within the elastic tissue layer and when this begins to proliferate the connective tissue follows the path of least resistance and protrudes into the duct

lamina, giving rise to the typical intracanalicular fibro-adenoma. The nature of the stimulus causing this proliferation is not definitely known. Since the tumors appear only after puberty, the assumption is that one or more of the newly secreted ovarian hormones may be responsible. Some corroboration of this has been produced by Lewis and Geschickter, who demonstrated large amounts of theelin in a fibro-adenoma. Turner and others have demonstrated proliferation of duct epithelium and extension of the duct system following injection of theelin in experimental animals; but localized tumors have not been produced. Whatever the stimulus may be, it is probably the same with both types of these solid tumors with the extra-elastic connective tissue being more sensitive to it at first or during the earlier years of menstrual life.

Both types of tumors may be single or multiple or bilateral. They may vary in size, from a small nodule barely palpable to a tumor 10 cm. or more in diameter. They are characterized by the fact that they are completely encapsulated, freely movable, not attached to the overlying skin and may be separated from the rest of the breast parenchyma. Very often they involve that projection of breast tissue pointing toward the axilla. As the tumor increases in size it replaces normal breast parenchyma so that with a large tumor very little gland may be left to function. Upon gross section of a simple fibro-adenoma the cut surface is white to pink in color, firm, and the small, round punctate areas representing the duct openings may be seen with the naked eye or with a hand lens. The cut surface of an intracanalicular tumor is also white but on spreading the tissue between the thumb and fingers of each hand a series of clefts and cracks is seen. These are the distorted and elongated ducts formed by the protrusion of the proliferating connective tissue into their lumina. Microscopically the simple fibro-adenoma presents a background of connective tissue in which are embedded varying numbers of small round or ovoid ducts. The relative amounts of fibrous tissue and ducts vary, depending upon the degree of proliferation of the latter. Epithelial

omas tend to appear within a few years after puberty while the majority of the intracanalicular type are found later on, usually after the age of twenty-five. There may be no sharp distinction between the tumors, and a simple fibro-adenoma quite often has areas of intracanalicular change in it. The writer feels that the simple fibro-adenoma, if left alone, will later become an intracanalicular one. The frequency of these is difficult to determine. In the Laboratory of Surgical Pathology of Washington University, their incidence was about equal to that of carcinoma of the breast and both the simple fibro-adenoma and the intracanalicular one occurred with about equal frequency. This may or may not be the experience in other clinics, but the general opinion is that these solid benign tumors are being seen more frequently than they were twenty-five or more years ago. The reason for this is largely due to the dissemination to the lay public of information concerning cancer. With the general realization that early cancer of the breast can be cured, more women are seeking medical advice much sooner after first noticing a lump in their breasts. This means that breast lesions are being seen earlier in their course and more of the benign tumors are encountered.

The cause of the growth is known in part. According to Cheatle, the simple fibro-adenoma is the result of the localized proliferation of the pericanalicular connective tissue. In his studies he has identified the fine layer of elastic tissue that surrounds the ducts and even some alveoli. Immediately outside this layer is the peculiar cellular connective tissue intimately associated with the ducts. This connective tissue is not the same as the interlobar connective tissue which acts as the general supporting framework of the whole gland. In response to some stimulus, so far not definitely known, this pericanalicular or periductal connective tissue undergoes proliferation which remains localized and, hence, the whole mass is encapsulated. Similarly there is another layer of this same connective tissue immediately within the elastic tissue layer and when this begins to proliferate the connective tissue follows the path of least resistance and protrudes into the duct

lamina, giving rise to the typical intracanalicular fibro-adenoma. The nature of the stimulus causing this proliferation is not definitely known. Since the tumors appear only after puberty, the assumption is that one or more of the newly secreted ovarian hormones may be responsible. Some corroboration of this has been produced by Lewis and Geschickter, who demonstrated large amounts of theelin in a fibro-adenoma. Turner and others have demonstrated proliferation of duct epithelium and extension of the duct system following injection of theelin in experimental animals; but localized tumors have not been produced. Whatever the stimulus may be, it is probably the same with both types of these solid tumors with the extra-elastic connective tissue being more sensitive to it at first or during the earlier years of menstrual life.

Both types of tumors may be single or multiple or bilateral. They may vary in size, from a small nodule barely palpable to a tumor 10 cm. or more in diameter. They are characterized by the fact that they are completely encapsulated, freely movable, not attached to the overlying skin and may be separated from the rest of the breast parenchyma. Very often they involve that projection of breast tissue pointing toward the axilla. As the tumor increases in size it replaces normal breast parenchyma so that with a large tumor very little gland may be left to function. Upon gross section of a simple fibro-adenoma the cut surface is white to pink in color, firm, and the small, round punctate areas representing the duct openings may be seen with the naked eye or with a hand lens. The cut surface of an intracanalicular tumor is also white but on spreading the tissue between the thumb and fingers of each hand a series of clefts and cracks is seen. These are the distorted and elongated ducts formed by the protrusion of the proliferating connective tissue into their lumina. Microscopically the simple fibro-adenoma presents a background of connective tissue in which are embedded varying numbers of small round or ovoid ducts. The relative amounts of fibrous tissue and ducts vary, depending upon the degree of proliferation of the latter. Epithelial

and connective tissue cells are all uniform in appearance and no microscopic evidence of malignant growth is made out. In the intracanalicular fibro-adenomas the connective tissue stroma contains many irregular clefts, cracks and slitlike spaces which are lined with cuboidal epithelium. These are ducts seen in an ordinary fibro-adenoma, but here collapsed and distorted by the growth into them of the proliferating intra-elastic connective tissue, pushing the lining epithelium as it grows.

If undisturbed certain changes may take place in both these tumors, the first being lactation hyperplasia. The duct system in either type of fibro-adenoma will undergo the same degree of proliferation as the rest of the breast. Ducts elongate and alveoli sprout at the ends of them. The secretion, however, accumulates in this abnormal duct system because it is not connected with any of the normal lactiferous ducts and the lactation hyperplasia persists in the tumor area long after the normal part of the breast has undergone postlactation involution. The pain associated with this trapped secretion is marked, because it causes marked dilatation of the ducts and the resultant pressure from this distention induces pain. Quite often a patient has been unaware that she harbored a fibro-adenoma until its great increase in size and persistence due to lactation hyperplasia made it noticeable.

Another change is that occurring mostly in the intracanalicular type of growth. This is a myxomatous change in the connective tissue which may be so marked as to give the cut surface of such a tumor an irregular mucoid appearance. Accordingly, the term *intracanalicular myxoma* or *fibromyxoma* has sometimes been applied to them. This same change may occur in the simple fibro-adenomas, but must be very uncommon, the writer having seen it only once. This myxomatous change is assumed to be due to some interference with the blood supply of the tumor. The third possible change in a fibro-adenoma is malignant proliferation of the connective tissue, resulting in a sarcoma. When encountered this has always occurred in the intracanalicular fibro-adenoma and

Bloodgood stated that he had never seen this malignant transformation in a woman younger than twenty-five. In our experience it has always occurred in much older women and never in the simple fibro-adenomas. As far as can be determined, malignant proliferation of the duct epithelium (carcinoma) in either of these solid tumors has not been found.

The differential diagnosis, then, of the fibro-adenomas concerns itself with separating them from the carcinomas and the determination of whether or not they are malignant. An early or small localized area of carcinoma may have some of the characteristics of the fibro-adenomas, such as lack of pain, mobility, absence of palpable or lack of enlarged lymph nodes and nonretraction of the nipple. However, most of the carcinomas will have enough infiltration into the surrounding tissue to give some degree of flattening of the overlying skin. Neither will transilluminate and where the age incidence is not an important factor an aspiration biopsy can be done or, preferably, an exploratory operation with excision of the suspicious mass and a surrounding zone of normal parenchyma. When we consider the size of the fibro-adenomas as usually seen, a carcinoma of similar size should ordinarily give some of the unmistakable signs of malignancy. To determine whether or not an intracanalicular fibro-adenoma is already malignant, the best method is excision and direct examination. Presumptive evidence is a solid tumor known to have been present for a long time (as much as several years) in a patient well along in adult life, who has noticed a recent, sudden, rapid increase in the size of the tumor.

Chronic Cystic Mastitis.—In a group by itself is the condition usually referred to as chronic cystic mastitis. The discussion concerning its nature has been active ever since Cooper first described it in 1837. We are perhaps beginning to understand some of the factors in its etiology but our main interest in it still lies in the fact that it may be a forerunner of carcinoma. The frequency of chronic cystic mastitis cannot be determined. No doubt a small percentage of the cases come to the doctor's attention. As will be pointed out later,

some of the changes included under this disease may be found in more breasts than hitherto suspected, in women approaching or passing through their menopause. Unless there is marked pain associated with the disease or unless the envelope of fat surrounding the breast parenchyma is absent or very thin, thus allowing her to detect the lump by palpation, a woman may harbor the condition without being aware of it. It is found almost always in women, but one does occasionally encounter a dilatation of the ducts in the breast of a male which may give rise to a tumor and the gross and microscopic picture of chronic cystic mastitis. It is always a disease of adults and the majority of the cases are found from about the age of thirty-five on. This is especially true of the cystic forms of the disease. Infrequently, diffuse solid masses are found in the breasts of younger women but these are often found to be due to connective tissue or alveolar epithelial proliferation with nothing more than moderate dilatation of the ducts. Previous lactation seems to have no bearing on its appearance. Its exact cause is not known but present-day evidence points more and more to its being the result of some disorder in ovarian secretion.

As a result of Taylor's careful studies we recognize the fact that there is no constant microscopic picture of a resting breast. The relative amounts of connective tissue, alveolar and duct epithelium vary greatly in normal or symptomless breasts. We do feel that there is some response in the breast to the changes in ovarian hormone activity incident to menstruation. Some feel that the changes grouped under chronic cystic mastitis are the end-results of the cumulative effect of this ovarian activity. This has been corroborated experimentally where dilatation of the ducts and desquamation of their lining epithelium has been produced following injection of smaller animals, notably mice, with theelin. Such a picture simulates chronic cystic mastitis. At any rate the disease most often makes its appearance at a time when the sex hormone balance of the woman is undergoing a marked rearrangement. Instead of there being a simple regression of the breast com-

ponents, as probably occurs in most cases, there is a proliferation of the connective and epithelial tissues, with the resultant varying picture included under this term. The disease is usually a slowly progressing one and it may or may not be attended with pain. The lesions are felt as lumps or isolated areas of increased hardness in the breast. They may be multiple or bilateral, but usually are single and involve only one breast. No satisfactory explanation of this has been made and it is one of the objections to the idea that the process is in response to ovarian hormone imbalance. If that were the case one would expect the process to be diffuse and bilateral. Extreme cases have been described where a large cyst or series of cysts have ruptured through the skin resulting in persisting sinuses. These are rare today. Instead we see a breast with a diffuse area of hardness due to small multiple cysts, connective tissue and small duct proliferation. This is the type in which we see more epithelial proliferation and often localized groups of small ducts are seen resulting in the picture referred to as nonencapsulated adenoma or fibro-adenoma. Into some of these dilated ducts or small cysts there is desquamation of lining epithelium and into others a papillary proliferation of lining epithelium. In other cases there is the large single cyst, often referred to as a blue-dome cyst, surrounded by a number of smaller ones in the neighboring firm parenchyma. These large cysts usually have a smooth, glistening lining which is made up of a single layer of epithelial cells. Papillary epithelial proliferation into such large cysts is not so frequent. Occasionally small cysts are found lined with large cells with markedly eosinophilic cytoplasm, with or without papillary proliferation. These have been interpreted by some as modified sweat gland cysts or adenomas. In other instances, the firm mass is found to be due to diffuse proliferation of the pericanalicular connective tissue, embedded in which are slightly to moderately dilated ducts, the latter often containing desquamated epithelium. Usually no epithelial proliferation is seen here and this type of change is more frequently found in younger women. Cheatle has given this the term of *mazo-*

plasia and finds that it may persist for many years with no tendency to malignant transformation.

The diagnosis of chronic cystic mastitis is made on the history of a slowly progressing, diffuse area of hardness in the breast, which may or may not be associated with pain. One is struck by the fact that most of the patients with this lesion have thin breasts where the fatty envelope is atrophic, thus allowing the individual to detect an area of hardness that a woman with fat breasts could not feel. Where the mass is felt in the latter type of breast, it is usually very large and more often associated with pain. The age of these women is important in that they are approaching or passing through their menopause or are still menstruating beyond the age when the menopause should be expected. In addition to this, the local findings are those of a diffuse or poorly localized tumor in the breast. This is not as freely movable as a fibro-adenoma and cannot be as easily separated from the breast parenchyma. In marked cases the mass may seem adherent to the deeper layers of the skin, thus simulating carcinoma. If there are one or more large cysts the intracystic tension is so great that the sense of fluctuation cannot be elicited. Transillumination may reveal a large cyst but not always the smaller ones, especially if there is marked fibrosis of the surrounding parenchyma. Aspiration should result in the recovery of cyst contents, if the cyst is punctured. One should not lose sight of the fact, however, that carcinoma may develop in chronic cystic mastitis and that the recovery of cyst contents does not exclude carcinoma in the neighboring gland tissue.

The differential diagnosis of chronic cystic mastitis concerns itself with the exclusion of the fibro-adenomas, carcinomas and possible sarcomas.

The simple fibro-adenoma occurs at a much younger age than the usual chronic cystic mastitis. Pain may be present in both, but in the former the mass is encapsulated, freely movable, and not attached to the skin, a finding usually not present in chronic cystic mastitis. With the fibro-adenoma transillumination gives a solid shadow, while with the other,

light may be transmitted. The next possible step is aspiration with the recovery of cyst contents if a cyst is entered, otherwise the results may be inconclusive. Usually one does not have to go so far in diagnostic procedures because the age, encapsulation and mobility identify the fibro-adenoma. With an intracanalicular fibro-adenoma the only other difference is the possible higher age incidence.

Carcinoma.—Much of the discussion about chronic cystic mastitis has been due to its confusion with carcinoma. In many respects it is impossible to differentiate between chronic cystic mastitis and an early or moderately advanced carcinoma without operation and microscopic examination of the tissue. Both occur during the same age periods, both are nonencapsulated, diffuse, cannot be separated from the rest of the breast parenchyma and are attached to the depths of the skin in many instances. In early carcinoma, absence of enlarged axillary glands means nothing. Transillumination may be inconclusive, depending on the size of the cysts, and aspiration may not always be positive as a small area of cancer may be missed. Here again the final appeal is carried to exploratory incision and examination of the completely excised suspicious area. These same diagnostic procedures are necessary to determine the presence of sarcoma.

The Relation of Chronic Cystic Mastitis to Carcinoma.—Ever since its description by Sir Astley Cooper one hundred years ago, discussion has concerned itself with whether chronic cystic mastitis is inflammatory or neoplastic. The consensus today favors the latter but opinion varies as to its relation to carcinoma. Ewing points out that in his experience about 50 per cent of the breast specimens excised for chronic cystic mastitis show proliferative changes that he interprets as definitely precancerous. He also makes the observation that very few breasts removed for and containing cancer "fail to show phases of chronic (cystic) mastitis in the outlying portions of the parenchyma." This has also been the writer's experience and he feels that in dealing with a possible chronic cystic mastitis one should always remember that such a lesion is

potentially malignant, at least where it is marked enough to give rise to a tumor or definite clinical symptoms. With more attention being paid to the prevention of cancer, the definite relation of this disease to chronic cystic mastitis should determine our course of treatment of the latter when it is encountered.

Carcinoma of the Breast.—Of the diseases of the breast, this is, of course, the most important. Its frequency cannot be exactly determined. We may get some idea of this from the mortality statistics; the last compiled for the United States being for the year 1933. In that year 128,489 deaths occurred due to malignant disease. Of these the deaths due to carcinoma of the breast were 12,484, this number being exceeded by carcinoma of the stomach, 26,566 and of the uterus, 15,221. All these show increases over the preceding years. Roughly, one might say that there are about 20,000 new cases of cancer of the breast in this country each year. The relative frequency to other diseases of the breast has varied greatly in recent years. A generation ago nearly 90 per cent of the breast tumors seen were malignant. Today less than 50 per cent of the tumors of the breast seen in consultation are malignant and if one includes chronic cystic mastitis as a breast tumor, the percentage of cancer is even lower. This is partly the result of the campaign begun twenty years ago by Bloodgood and Cullen to enlighten the lay public about cancer, and the realization by the public that early cancer of the breast can be cured. Women are seeking medical advice sooner after first discovering the lump in their breasts, hence more benign lesions are seen and cancers are seen earlier in their course. The disease is found mostly in women, only 1 per cent of cancers of the breast being found in males. Cancer of the breast is a disease of adult life and occurs most frequently in that decade when the menopause usually takes place, between forty and fifty. This may vary somewhat from clinic to clinic. In Harrington's carefully studied series of 4038 cases, 51 per cent were in women under fifty years of age. If one were to plot a curve of age incidence, the peak of such a curve would probably be be-

tween forty-five and fifty years. The youngest case recorded was in a girl of seventeen and it has been seen in women over eighty. Below thirty its incidence is very uncommon, but after thirty-five there is a rapid rise in frequency which remains high until fifty-five. Previous lactation, as far as can be told, does not influence the disease, as it is found in women who have never lactated. Lactation hyperplasia occurring at the same time the cancer is discovered influences the prognosis adversely since in such a breast with its abundant blood supply and increased lymph drainage the disease runs a very rapid course and instances of cure by any means are exceedingly rare, if they occur at all. The relation of ovarian function to the growth of cancer is not yet well understood, but there is certain evidence pointing to such a relationship. The observation was first made fifty years or more ago that the disease ran a relatively less malignant course in women who had ceased menstruating. This formed the basis for the oophorectomies done years ago in these women in addition to removal of the tumors. Somewhat later the artificial menopause was produced by x-radiation and in recent years Dresser has renewed this work. Further evidence is the experimental production of cancer of the breast in male mice following the injection of folliculin (theelin) first done by Lacassagne and since repeated by many others. According to Novak about 6 per cent of women pass through their menopause after the age of fifty. In a series of cases of cancer of the breast occurring in women beyond the age of fifty, the writer found that over 50 per cent of these women, instead of the expected 6 per cent, had such a delayed menopause. The only conclusion to be arrived at from all this is that ovarian function, through the elaborated hormones, is a factor, so far not completely understood, in the production of cancer of the breast. Trauma in the sense of a single injury has never been definitely proved to cause cancer. The chronic irritation of repeated minor insults may do so, but where a single injury is suspected of doing it, the presumption is that the lesion was already present and was aggravated or attracted attention by the blow.

Heredity has been recognized in recent years as one of the factors influencing the development of cancer. Many instances have been observed of so-called "cancer families" and the work of Slye has placed this on an experimental basis.

Cancer of the breast may arise from the epithelium in any part of the organ, the larger lactiferous ducts, the smaller ducts immediately draining the alveoli, or the alveoli. In the majority of cases the malignant proliferation starts in the smaller ducts. These are the ones usually dilated to form cysts in chronic cystic mastitis. There is a varying degree of connective tissue proliferation accompanying the cancer. The relative amount of this determines whether the tumor has the gross and microscopic characteristics of a scirrhus or medullary cancer. In the former there is abundant fibrous tissue proliferation and in the latter less. Often the two cannot be differentiated in the gross, and microscopically both may be seen in the same primary tumor. Less importance is placed on this differentiation today than in the past. The main thing is that the tumor is malignant. When the process arises in the alveolar epithelium it takes the form of an adenocarcinoma. Cancer arising from the lining of the larger ducts, according to some opinions, also gives the picture of adenocarcinoma. The writer feels that this is not so and that instead the malignant tissue confines itself to these larger ducts, giving the picture of a so-called duct cancer. The medullary and scirrhus cancers together make up most of the breast cancers, only 15 per cent being adenocarcinomas, and the other unusual types are found very infrequently. Grossly the tumor is nearly always single and begins as a painless lump. Pain is a relatively late symptom. Usually one breast is involved although simultaneous bilateral cancer does occur. This is quite uncommon, but when it does happen, the prognosis is very poor. Cancer may occur in a surviving breast, after the other has been removed or treated for the same disease. Naturally, the shorter the period between the appearance of the first and second tumor, the less favorable is the prognosis. Where the period is of any appreciable length one may assume that the

second tumor is a cancer independent of the first. It does not necessarily follow that the second is a late recurrence of the first. The gross and microscopic picture of the second tumor may differ from that of the first. The usual description of a carcinoma of the breast, retraction of the nipple, axillary metastasis, dimpling of the overlying skin, etc., applies to fully developed and advanced cases and is so well known that it need not be repeated here. We are concerned with the early cases, where the above characteristics have not yet made their appearance and about all we have to deal with is a small lump in the breast. This is usually painless, freely movable, most often not attached to the skin and not accompanied by axillary metastasis. The presence or absence of the latter is of great importance in the prognosis. In the series recently reported by Harrington, 71 per cent of the patients with cancer of the breast without axillary metastasis were living five years after operation, 55 per cent lived ten years after operation and 40 per cent were alive fifteen years after. With axillary metastasis present at the time of operation only 26 per cent lived five years or more, 13 per cent were living after ten years and 9 per cent lived fifteen years postoperatively. With all the scattered information we have today concerning this disease, the presence or absence of axillary metastasis is the most important factor we have in estimating the prognosis, yet today about 72 per cent of the patients with cancer of the breast, when first seen, already have axillary metastasis. This merely means that our patients are seeking medical advice still quite late in the course of the disease. Harrington found that the average length of time elapsed between the discovery of the lump in the breast and the seeking of medical advice, even in recent years, was fourteen months. In some individual cases that period had been several years. This certainly means that our patients are not yet being seen as early as they should be.

The diagnosis of carcinoma of the breast is based on the patient's history and physical findings. The usual history is that of a painless lump in the breast, often accidentally discovered and growing slowly. In the early cases the findings

may not be characteristic, that is, nothing but the tumor mass or area of hardness is felt and the findings of advanced carcinoma, such as attachment to the skin, dimpling of the skin, lack of mobility, and retraction of the nipples, are missing. Transillumination may show a dense area that does not transmit light. Aspiration biopsy may show the malignant cells, but negative findings do not rule out carcinoma. The differential diagnosis is the ruling out of any benign lesion and these are solid tumors, such as the fibro-adenomas, and chronic cystic mastitis. This should not be difficult when we are dealing with a well-developed cancer, but with the small or early lesions a differential diagnosis cannot be made until the tumor or tissue from it is examined grossly or microscopically. Transillumination may show a large cyst, but it cannot give definite information about a small solid tumor. Another minor diagnostic procedure is the aspiration biopsy. This is the removal of a very small bit of the suspected tissue through ordinary or specially adapted hollow needles by means of suction. In the hands of some this has given very satisfactory results. In order to obtain tissue for a corroborative diagnosis of a clinically definite cancer of the breast which is to be radiated, we feel that it is of value, but we also feel that its value is questionable when resorted to as the final means of diagnosis in early or doubtful cases. With a small tumor, if we obtain malignant tissue, all well and good, but in a small tumor the actual area of cancer may be missed. We also feel that this method should not be used unless, if malignancy is proved, active treatment, whether surgical or radiological, is to be instituted immediately. Traumatization of a malignant lesion may increase the rate of growth and should be avoided. We have preferred, in the small or early tumors, or those where direct examination of the tissue is necessary, to excise the suspicious area with a good zone of normal neighboring gland. One should be very careful not to incise the tumor itself. This excision of the tumor can very often be done under local anesthesia through a small skin incision, but it should always be done in the operating room with the patient prepared for a

a mastectomy, if the tumor is found to be malignant. The nodule is removed it is handed to the attending surgeon or pathologist for examination or, what is better, if the surgeon is as well grounded in tumor pathology as he should be, he bisects the tumor and makes the diagnosis from the gross appearance. If the tumor is malignant, he must, of course, wash his hands, gown and gloves before proceeding further. The person examining the tissue must be trained in tumor pathology, whether he be pathologist or surgeon. If the tumor to him is definitely malignant on gross examination, then it is a routine case and the patient's interests are best served by closing the wound and waiting twenty-four to forty-eight hours for well prepared paraffin sections, which can then be examined by the pathologist at his leisure and without the feeling that he must hurry because a patient is waiting on the operating table until his diagnosis is made. We have never felt that a frozen section can tell one more than can be seen with the unaided naked eye. If the diagnosis cannot be made with the frozen section, then well fixed and prepared sections are in order. We have occasionally seen the diagnosis of chronic cystic mastitis made on a single frozen section and nothing more done to the patient. Then when the rest of the excised tissue has been carefully examined by means of sections taken from several areas, a small zone of cancer has been found and unless this possibility has been provided for, the patient has to be told of the earlier mistaken diagnosis and urged to submit to the radical operation.

Because of lack of space the above discussion has had to be brief and many lesions not commonly met with in the breast have not been referred to. An earlier article by the writer goes into these in more detail. Our main problem in diseases of the breast is to recognize cancer and to do it as early as possible. A lump in the breast should never be temporized with. Even today, too many women are seeking medical advice with lumps in their breasts which they have been aware of for some time and in many instances their medical advisers have not insisted on immediate diagnosis and treatment, but because of the pa-

tient's age or lack of faith in operative cure for cancer, or other reasons, have preferred to watch the lump from time to time. We feel that every lump in the breast in an adult woman should be considered malignant until definitely proved otherwise. No doubt there are many practitioners who can do this by the ordinary means at their disposal, but with the increasing frequency with which we are seeing these early questionable lesions, we feel that the coordinated efforts of the patient's personal physician, the pathologist, the radiotherapist and a surgeon who has special training in neoplasms are necessary. To fill these needs the so-called "tumor boards" or "tumor clinics" have been organized in many hospitals and medical centers. There such cases are seen, studied and discussed and a plan of treatment agreed upon, depending upon the findings in each particular case. With the diagnosis and treatment of early cancer our goal, and with diagnosis and treatment organized in such a manner today, we feel that in many of the instances the responsibility is too great for the physician to assume alone.

CLINIC OF DRS. MARTIN F. ENGMAN, RICHARD S.
WEISS AND MARTIN F. ENGMAN, JR.

SCHOOL OF MEDICINE, WASHINGTON UNIVERSITY

ECZEMA AND ENVIRONMENT

ONE of the most frequent diseases of the skin met with in general as well as in dermatological practice is "eczema" or "dermatitis." These terms are used almost synonymously. However, the term "dermatitis" includes "eczema" in that the former word is used in connection with certain other diseases not related to eczema at all. When the true cause of the inflammation is known, the word dermatitis is usually used with a preceding modifying word, *e. g.*, "contact dermatitis." If, however, the cause is undetermined, a general diagnosis of "eczema" is offered as a name for the condition (Norman Walker).

Under the heading of "eczema" may be included a group of simple inflammations of the skin. Since there are a number of unrelated factors involved in the production of a rather wide variety of clinical pictures, "eczema" does appear to be a group rather than a single disease.

The Clinical Picture.—This depends upon both the type of lesion present and the distribution. The appearance varies from an acute, red, weeping surface to a chronic, thickened scaly skin with accentuation of the natural lines commonly called "lichenification." The primary lesions are usually vesicles and occasionally simple erythema. The intense pruritus associated with these lesions results in traumatizations of various kinds, which alter the picture; for instance, the scratching in the vesicular types of the eruption produces secondary in-

fection (papules and pustules), and crusting follows. The erythematous types may become vesicular and a similar picture supervenes. In the more chronic or subacute types thickening of the skin and scaling may appear.

The distribution may vary from an entirely local inflammation, acute, subacute or chronic, to a partly or fully generalized eruption. It may be symmetrical or asymmetrical, depending upon the factors influencing its production. A bilateral and symmetrical distribution may often imply a circulatory dissemination of the causative agent. The asymmetrical eruptions are usually of external origin.

The Histopathological Picture.—In a few words this may be summarized as follows:

The epidermis and the corium are both involved in a primary edema. In the epithelium this edema is extracellular and intracellular with "balloon" degeneration, thus producing intra-epidermal vesicles. In very acute, weeping eczema the keratinized layer may be lost entirely. If it be present, there is often parakeratosis. Due to hypernutrition, the rete may be thickened and the pegs elongated (acanthosis). In more chronic cases there may be hyperkeratosis. The upper cutis shows engorgement of the vessels, general edema and often a cellular infiltration. The histopathological picture, of course, depends largely upon the acuteness or the chronicity of the disease.

Etiology.—Eczema occurs in individuals of all ages and both sexes and from a wide variety of causes. The mechanism involved may be divided roughly into three types. First, ordinary irritation, such as may occur in the majority of people from the application of strong chemicals. Second, that type of specific hypersensitivity named "atopy" by Coca. Third, contact dermatitis.

It is pertinent here to mention certain fundamental differences between these latter two types of hypersensitivity, because the mechanism involved is quite different. Coca contrasts these two diseases very strikingly. Atopy appears to be an antigen antibody reaction. At least in the blood of the

atopic individual the presence of "reagins" may be demonstrated by passive transfer of specific sensitivity to a small area of skin in a normal nonsensitive individual. Heredity is of prime importance in the development of atopy. Furthermore, only 7 per cent of whites are subject to atopy in any form, including hay fever, asthma, migraine, etc. Urticaria is the most usual type of atopic skin reaction. Eczema is very rarely, but may be, of atopic origin.

Contact dermatitis accounts for the greater number of eczema cases. In this disease the mechanism is unknown but reagins are not demonstrated to be present by the passive transfer test. Heredity is a factor of minor importance in the production of this sort of hypersensitivity, since it has been shown by Bloch and others that at least 70 per cent of the white race may be sensitized at will to certain contact agents.

The work of Brown, Milford and Coca on contact dermatitis due to ragweed pollen throws light on another phase of this problem. These investigators found that in cases of eczema due to ragweed pollen the patch test was positive with protein-free oil extracts of the pollen, but scratch and intradermal tests with pollen protein were negative. The exact reverse was found in cases of hay fever due to ragweed pollen. Thus, they showed that eczema was due to the pollen oil and that atopic hay fever was due to the pollen protein.

Rôle of Trauma.—Trauma plays a major rôle in the production of eczema. It is an extremely pruritic disease and mechanical trauma, such as rubbing and scratching, is always indulged in by the patient. This increases the inflammation, denudes the surface, and may be the most important factor in starting secondary infection. Strong irritating local applications, such as sulphur, tar, resorcin, mercury, and other chemicals, may be sufficient in themselves to cause inflammation. These are applied to an already inflamed surface so that the resulting acute inflammation may mask whatever underlying condition is present.

The state of the skin capillaries must also be considered here. Peterson has studied capillary permeability by means

of the cantharides blister test and by qualitative and quantitative analysis of the protein content of the tissue juices found in the blister fluid. He reports that differences of capillary permeability are present in individuals of different types and also in various general constitutional conditions and diseases. Our clinical studies indicate that capillary permeability is particularly increased over the entire surface of the skin when any part of it is involved in an inflammation, such as eczema. As a result, at such a time the skin will be much more reactive and more easily inflamed by any trauma.

The importance of trauma may be illustrated by the following case:

A child two years old with a generalized eczema was found to be sensitive to the ingestion of wheat. The eating of a cracker would produce an intense itching over the body. The baby was put in the Barnard Free Skin and Cancer Hospital for treatment and study. Wheat was removed from the diet and local applications applied. When the skin was completely free from eruption, the following experiment was performed. The left arm and leg were dressed in a stiff, thick, crinoline bandage and 2 wheat crackers fed the child. Within two hours there seemed to be an intense pruritus all over the body. The child rubbed and scratched vigorously and by next morning patches of eczema were present all over the body. However, when the dressing was removed from the left arm and the left leg, there was no evidence of any eruption whatsoever in the covered areas. It was concluded that ingestion of wheat, to which the patient was sensitive, produced an allergic pruritus and that the severe trauma of rubbing and scratching on the already disturbed skin (increased capillary permeability) caused the visible signs of eczema. The fact that no eruption occurred under the covered areas demonstrated that the visible lesions on the uncovered portion were due to trauma. Probably most allergic infantile eczemas are produced in much this same way. We have performed similar experiments several times and have obtained similar convincing results.

Eczematids.—There are many diseases in which a general-

ized secondary eruption occurs as a result of the dissemination of micro-organisms from a primary focus. These are often referred to by the suffix "id." As examples there are syphilids, tuberculids, epidermophytids, etc. Toxic substances may produce an "id" in a similar manner. Denny has reported generalized secondary eruptions in cases of local picric acid dermatitis. We refer to this phenomenon in cases of eczema as "eczematid." Eczematids are far from infrequent. They are due probably to the absorption of toxic products at the site of the primary acute eczema. Whether such an inflammation produces something toxic to normal cells, what these toxins are, and whether they are absorbed into the general circulation are questions of theoretical nature and not as yet proved. Reasoning, however, by analogy it seems a likely explanation of the basis of the eczematids. As was mentioned before, there is a generalized increase of capillary permeability. These toxic substances escaping from the capillary bed into the papillae of the skin cause local insult and death of cells in the upper cutis and epithelium with a resulting acute inflammation. For example, in varicose dermatitis of the legs a secondary eczematid is frequent on the backs of the hands and arms, symmetrically distributed. The eczematid may be quite generalized, as in the following case.

Illustrative Case.—A woman forty-five years of age applied a mustard plaster of her own making to her chest as treatment for upper respiratory infection. This resulted in the burning of an area of skin about 6 inches square. The area was covered with large bullae, was red and edematous, with a weeping exudate which dried forming a crust. In the course of the next few days there appeared a generalized symmetrical eruption consisting of groups of tiny papules and dry vesicles.

This latter eruption was evidently due to the absorption of toxic products from the initial lesion on the chest. Since capillary permeability over the entire skin was greatly increased, the dissemination of toxic products to all parts of the skin was accomplished via the blood stream. The cells sur-

rounding capillary beds in the papillae were bathed in lymph containing these toxins and the generalized inflammatory reaction (eczematid) resulted.

Hereditary Diathesis.—There are undoubtedly people born into the world with a distinct hereditary predisposition to eczema, just as there are hereditary predispositions to tuberculosis, cholecystitis, hypertension, and other diseases. This predisposition was originally called by Czerny "exudative diathesis." Such a patient may begin with eczema in his first month and continue with outbreaks during childhood, during puberty, or throughout life. The skin of such an individual seems to be highly reactive, so that inflammation may be easily produced by both specific and nonspecific causes. The skin capillaries are easily thrown into a state of increased permeability and the physicochemical equilibrium of the skin is quite easily upset. Such a patient may have a whole list of specific sensitivities, and contact dermatitis may be produced by a variety of agents. Atopy may sometimes be a factor in this condition. The ordinary wear and tear of life, such as heat and cold, sun and wind, dust, soap and water, secondary infection, and other irritating factors are of varying importance. Thus, the study of a case of chronic exudative diathesis is very difficult, and all the factors mentioned in connection with eczema have to be taken in consideration. Patch tests are particularly deceptive because false, nonspecific positive results are often obtained. The same may be said of intradermal and scratch tests with protein extracts of atopic antigens.

Constitutional Factors.—Opinion is divided as to the importance of constitutional factors in the production of eczema. Adamson believes that the disease is entirely external. Ingram, however, points out that many constitutional conditions influence the course of eczema and are sometimes the underlying cause. One of us (Engman, Sr.) has emphasized for many years the importance of the general constitutional condition in eczema patients. Such diseases as nephritis, hepatitis, hypertension, heart disease especially with early de-

compensation, tuberculosis, diabetes, thyroid dysfunction, and so on, cause sufficient disturbance of the general constitution to produce disequilibrium of physicochemical relations in the skin, particularly changes in capillary permeability. The skin, as much a part of the body as any other organ, is affected by functional disturbances. Eczema from any cause, or combination of causes, may result more easily in the skin of a patient suffering from certain constitutional disorders than in one whose general status is normal.

Illustrative Case.—The patient was a woman forty-three years old complaining of chronic eczema of the hands and feet. The skin of the palms and soles was chronically inflamed and markedly keratotic. The redness was sharply outlined at the borders of the palms and soles. Her general examination showed an increase in weight, slow pulse, vague muscular pains, sense of fatigue, nervousness, and a minus 20 per cent basal metabolic rate. Under proper thyroid medication all of these symptoms improved greatly and the eruption on the palms and soles cleared up in two or three months. This type of eczema we call "thyroid eczema" in that thyroid dysfunction is the underlying cause. The eczema is produced on the soles by much walking and on the palms by household work, such as washing clothes and dishes, polishing furniture, and scrubbing floors.

Illustrative Case.—The patient was a man sixty-five years old who had a dermatitis over the lower legs, ankles and on the backs of the hands, of several months' duration. General examination and electrocardiogram showed some myocardial changes and enlargement of the heart, but no very marked heart disease. The patient complained of severe itching of the legs. He had been using various strong patent preparations to allay the itching. The eczema cleared up rapidly under soothing local applications, rest, and small doses of digitalis.

The interpretation of this case is as follows: the myocardial changes reduced, somewhat, the efficiency of the heart. A very mild dependent edema resulted which was more or less

chronic. There was itching of the legs due to the microscopic edema in the skin with consequent trauma both mechanical (scratching and rubbing) and chemical (strong local applications). These factors produced an eczema on the legs, and an eczematid on the backs of the hands from the general increase of capillary permeability and absorption of inflammatory toxic products. Rest and digitalis improved the efficiency of the heart, which was the underlying condition, and since the traumatic factors were eliminated, the skin healed.

Secondary Infection.—Secondary infection is a contributory factor in a great number of eczema causes. An inflamed skin especially if excoriated may offer a fertile medium for certain organisms particularly the staphylococci. Pustulation may take place, or as the eczema clears up it may be followed by a series of furuncles.

Infection may be a primary cause of an eczematous eruption—eczematoid dermatitis as first described by Engman, Sr.

Handling of Patient.—The study of a patient with eczema follows no set rule. Each problem must be dealt with individually. There is, of course, always the possibility that the distribution of the eruption may give some clue as to the probable cause. For instance, eczema of the eyelids is usually produced in one of two ways: first, by local application of some cosmetic such as mascara or eyebrow pencil; second, by something with which the hands come in contact. It is a very human habit unconsciously to rub the eyes so that whatever the hands have on them will be rubbed on the eyelids.

Illustrative Case.—The patient was a woman thirty-two years of age, with an eruption around both eyes consisting mainly of an erysipelas-like, red edema extending in all directions from the eyelids for about an inch, and involving the lids themselves. Her physician had made a tentative diagnosis of erysipelas. However, the consultant decided the eruption was due to an external contact agent because the patient was feeling well, had no temperature, and the eruption was so exactly symmetrical. Mascara proved to be the causative agent.

Illustrative Case.—A neighborhood night watchman had

repeated attacks of eczema involving the left eyelid. It was quite difficult to discover what the causative agent might be. Wearing of gloves did not help the situation. Careful questioning as to the duties of this patient revealed that he carried his flash light in his right hand and would try the door of a store with the left hand, at the same time flashing the light through the window. A certain bank had a brass door pull, which was covered with brass polish occasionally. A patch test with this brass polish was positive. Evidently the left hand came in contact with the brass polish and later the patient would rub his left eye with his left hand.

History.—The history of the present eruption, of all past eruptions, especially of a similar nature, and of the general habits of the individual is, of course, the greatest source of data in solving any case. If the patient presents himself for advice as soon as the eczema appears, the trail is much more easily followed. The patient's memory is fresher regarding where he has been and what contacts he has made immediately preceding the appearance of the eruption. If many days since the onset have passed, it is much more difficult to obtain contact data, and it is sometimes necessary to wait for another attack, in order to trace the causative agent. Absolute co-operation on the part of the patient is most necessary. Strangely enough, this is frequently hard to get. Some patients refuse to devote any thought themselves to possible contacts. Such a person will answer questions indifferently, even hostilely, in which case it is next to impossible to make any headway.

Patch Tests.—The patch test offers great assistance in discovering the cause of eczema in many particular cases. The technic is simple. A suitable area of skin is chosen, such as the anterior forearm just below the cubital space, lateral surface of the upper arm, the anterior thigh, or the abdomen. In these areas the skin is perhaps delicate enough to make positive patch tests more likely. The material to be tested whether liquid or solid is placed on a small piece of gauze 1 cm. square. The gauze is applied to the intact skin and over

it is laid a piece of cellophane 4 cm. square. Adhesive is placed with a wide margin over the whole patch. Forty-eight hours later the patch is removed. There will be, in a positive test, a small square patch of eczema corresponding to the square of gauze. If adhesive irritates the skin, there will be a margin of clear skin around the center positive patch test. Thus, there will be no confusion as to what has produced the little patch of eczema. In case the patient is extremely sensitive to the material tested, there might be a very severe reaction if the patch is left on two days. Therefore, it is a good rule to remove the patch if the patient has very intense itching at the site of the test any time before the two days are up. Delayed reactions are sometimes encountered so that the test site should be watched for several days after the patch is removed.

The interpretation of positive patch tests is simple if one will consider two important points. First, there are many materials which will irritate the skin of most people. If such a common irritant is to be used for testing purposes, it is obvious that it must be in a sufficiently dilute solution so that the normal nonsensitive skin would not react. It is often necessary to control the test by applying the material in question in dilute solution to one or more normal subjects. Second, the interpretation of a positive patch test and its relation to the eczema under observation is analogous to the interpretation of a positive Wassermann in its relation to a lesion suspected to be syphilitic. True syphilitic lesions may be present and the blood may show a negative Wassermann test. On the other hand, a syphilitic with a positive Wassermann may have some other disease not connected with syphilis. Such laboratory tests are only an aid to diagnosis, and should not entirely govern the viewpoint of the clinical problem. It is quite possible that a patient may be sensitive to more than one thing so that though a certain material gives a positive patch test in a patient, that particular material may not have produced the eczema in question. These two factors in patch testing are very well illustrated in the following case:

Illustrative Case.—The patient was a young woman twenty-five years of age with an eruption on the cheeks, roughly corresponding to the rouge and powder areas. The most obvious probability was rouge and powder. Since these contain orris root a patch test was applied of orris root oil extracted after the method of Coca. The patch test was positive to a mild degree. The use of orris root free cosmetics did not improve the patient and it was discovered that the eruption was due to black gloves. A patch test with the black dye (paraphenylenediamine) was markedly positive. It was found on subsequent testing with orris root oil, that a mild positive reaction resulted in a certain per cent of normal non-sensitive individuals. Thus, our original interpretation of the positive orris root test was misleading and further study of the case was necessary.

Common Contactants.—It is important to note here some of the more common causes of contact dermatitis. These fall naturally into groups.

Cosmetics are of especial importance in reference to eczema of the face because of their universal use especially by women. The most frequent offending ingredients in cosmetics are orris root, perfumes, and pigments. Any cosmetic may be at fault, even the so-called "nonallergic" ones. Included in this group are the shaving preparations used by both sexes, hair dyes, hair tonics, finger nail polishes and enamels, and deodorants. Frequently a dermatitis may be caused by contact with a cosmetic on the skin of another person, as illustrated by the following cases:

Illustrative Case.—A man twenty-five years old developed a severe vesicular dermatitis on his lips and around his mouth. The cause of it proved to be a new brand of lipstick his fiancée was using.

Illustrative Case.—A middle-aged man presented himself with an eczema involving the face. For many months he reappeared at intervals with recurring attacks. Close inquiry revealed no contacts which had any etiological significance. During one acute attack, his wife appeared in the office with

him and it was quite apparent that she dyed her hair. Questioning revealed that the recurrences of the husband's eczema corresponded with the time of each fresh application of the wife's hair dye.

Dyes in general are frequent contactants. Dyes used in furs and clothing are common offenders.

Illustrative Case.—A housewife aged forty was seen in her home suffering from an acute vesicular dermatitis involving the face, neck, shoulders, extensor surfaces of the arms and forearms and the exposed area of the chest. Many remedies had been applied; several physicians had placed her on various diets. She was frantic with torturing pruritus. The disease had begun six months previous to our observation. History revealed that it came on shortly after the purchase of a new dress. A patch test with a fragment of the brown woolen material produced an extremely severe vesicular reaction. The patient discarded the dress and made a complete recovery in a few weeks.

Oliver reported the first case of dermatitis due to the rotogravure section of the Sunday newspaper. It is noteworthy that these cases have exacerbations on Mondays. Such cases are not infrequent.

Plants of many species are responsible for a large group of eczema cases. Both the plant pollen carried in the air, and the leaf itself may produce dermatitis. Of the pollens, ragweed pollen is the best known offender. Such cases are usually seasonal. Direct contact with plants such as poison ivy, sumach and primrose produces an almost universally recognized dermatitis. Rarely many other plants may also excite a similar dermatitis.

Household chemicals form a group very seldom detected. Among them are included insecticides, antiseptics, soaps, deodorant soaps, cleaning agents, furniture and floor polishes and house dust (probably since some of the above agents are contained in it).

Occupations of various sorts expose patients to many substances to which they may be or may become sensitive. For

instance, cement workers sometimes become sensitive to cement, painters to paint or some of its ingredients, candy makers to flavoring extracts, and so on.

To these groups might be added a miscellaneous one including imitation pearl beads, jewelry, wool, mohair, feathers, etc. Medicines, especially patent preparations, are universally used to treat various mild skin affections. Many times a true sensitization may be present and a contact dermatitis be produced rather than a nonspecific chemical irritation. Thus, a few mosquito bites may be converted into an acute eczema.

Treatment.—Obviously the first and most important step in treatment is to discover and if possible eliminate the cause of the dermatitis in the individual patient. Contributory causes as mentioned previously should also be sought for and eliminated. This procedure has been discussed. Local treatment is usually necessary and must be chosen to suit the requirements of the case. The best rule to follow in general is to use soothing applications. In very acute weeping cases cold wet applications are most relieving. In more erythematous cases and in subacute eczematous conditions lotions containing bland powder, creams, and bland pastes are useful. To allay the itching phenol in 1 per cent or at the most 2 per cent solution or mixture may be added to the lotions or ointments. Strong chemicals usually used for eczema, such as tar, sulphur, resorcin and salicylic acid, should be used with great caution, or better, not at all. Boric acid, oxide of zinc and corn starch are safer and give much better results. Secondary infection is relieved by adding 4 per cent xeroform to the applications.

WASHINGTON UNIVERSITY SCHOOL OF MEDICINE, BARNES
HOSPITAL, ST. LOUIS MATERNITY HOSPITAL AND ST. LOUIS
CITY HOSPITAL No. 1

THE TREATMENT OF GONORRHEAL VAGINITIS

GONORRHEAL vaginitis is understood to be an infection of the vagina caused by the gonococcus. This particular stage of a gonorrheal infection is rarely observed in the adult, as it seems to be only a transient phase in the development of this disease in the female. It certainly is more commonly seen in children and offers a very definite problem in therapeutics. As stated by Witherspoon¹, "The treatment of gonorrheal vulvovaginitis in infants and young girls has always been an unsolved problem to the gynecologist, the pediatrician and the general practitioner. The various methods of therapy—vaginal instillations and irrigations, antiseptic applications to the cervix, the application of heat, the use of suppositories, change of bacterial flora and the administration of vaccines—have offered so little encouragement in the eradication of this condition that many physicians consider that no treatment at all is of equal value. Therefore, it was with great enthusiasm and with a warm reception that those who came in contact with this disease welcomed the rational hormonal therapy first advanced by Lewis² in 1933.

"Lewis' method of therapy is based on logical clinical reasoning. Gonorrheal vulvovaginitis is usually limited to the prepuberal years. For reasons clearly explained by Schaufli³ and Kuhn³ on the basis of microscopic study, the immature

vaginal mucosa harbors the gonococcus in its crypts and offers a fertile means for its growth. With the onset of puberty and the conversion of the infantile vaginal mucosa into the mature, thickened stratified epithelium, the gonococcus no longer finds a fertile habitat, and the vulvovaginitis of childhood disappears. In fact, it is rare to observe gonorrheal vaginitis in a woman. The rationale of Lewis' treatment was the conversion of the infantile vaginal mucosa into the mature type by administering the ovarian follicular hormone."

In an excellent historical review of therapy in gonorrhea, Wehrbein¹ states, "We may also mention its complications and so be assured that it is a problem worthy of great efforts. But the efforts must be less primitive; the disease is not known well enough. Its course without treatment cannot even be approximately stated with statistical figures; even with treatment we do not know yet if the average case may be expected to last two months or six months. Our pathological knowledge of the disease is still deficient. Where are the gonococci, how long do they last in near or remote foci, how are they slain or if this is too much what are their living conditions *in vivo*? Until some of these questions are solved it will be an accident if we find the means of shortening a gonococcus infection materially and it will be a miracle if we find a specific treatment."

Schauffler,^{5, 6} and Schauffler and Kuhn³ have given us an excellent description of the anatomy of the immature vagina and have indicated the reasons for the limitation of the infection to the vagina without the usual involvement of the accessory glands thereof. The lack of development in these glands does not predispose to their infection. They speak of the immature vagina as the "harbor of infection." They state, "We know that, in the adult, the gonococcus is retained in the Skene's and Bartholin's and the cervical glands, and is frequently passed over from the cervical glands to the endosalpinx, while the vagina, except for a transient inflammatory reaction, is immune. We have shown that, on the other hand, in the infant and small child, the vagina is the point of election—the Skene's, Bartholin's and endocervical glands are rela-

tively noninfectable, and there is immunity of the endosalpinx secondary to that of the endocervix.

"It is not sufficiently clearly understood, even by those who have made something of a study of gonorrheal infections in infants, that the vaginal cervix is the seat of deep pleats and folds similar in all respects to those noted throughout the remainder of the vaginal wall, thus, the vaginal cervix is not exempt from an infection which involves the entire vaginal wall. This fact was early noted by Hess in a series of post-mortem examinations. Unfortunately, Hess' observation had been misconstrued. In his own report Hess carefully differentiates between the vaginal cervix and the endocervix. He reports infections of the vaginal cervix only. He has been broadly quoted to the effect that at postmortem he has demonstrated 'cervical infections,' with the inference that endocervical infection has been described. This inference is not justified. The use of the term 'cervicovaginitis' to describe such infection, while it is perhaps more minutely descriptive, we believe is misleading in that it suggests a frequent involvement of the endocervix as an accompaniment of vaginal infections. Endocervical infection as an integral part of the pathology occurs only in individuals who have reached a stage of advanced development of the cervical glands. It is perhaps an occasional transient accompaniment of severe acute infection of the immature vagina. The use of the descriptive term 'vulvovaginitis' is distinctly a misnomer. The vulvar irritation in these cases is completely secondary, and due to factors similar to those which cause external irritation in pyelitis, diarrhea, etc."

Ruys,⁷ in the discussion of the etiology of vulvovaginitis infantum, states that "the first question is whether or not it is a gonorrheal infection. The clinical picture of this infection is not typical enough to allow a diagnosis to be made without a bacteriologic examination. The diagnosis is almost always made on smears of the pus stained by Gram's method or only the methylene blue. Cultures are not considered necessary. As there are some cocci that resemble the gonococci more or less when different staining methods are used, the way to a

faulty diagnosis is open. Clauberg⁸ pointed out that many cases of vulvovaginitis were falsely considered gonorrheal infections. From 70 children with vulvovaginitis he could not cultivate gonococci. Gradwohl⁹ cultivated gonococci in only 2 out of 25 cases." Ruys found "the ascites-Levinthal-agar plates and blood-water-agar plates excellent mediums for the isolation of gonococci and tried to find out which part this microbe plays in the vulvovaginitis of children. All smears were stained by van Loghem's method. Since the diagnosis in children with vulvovaginitis is made by van Loghem's Gram method combined with the culture method, the number of children treated for vulvovaginitis gonorrhoea in the Amsterdam hospitals has been reduced from approximately 450 a year to twelve a year." Her conclusions were that "in many cases of vulvovaginitis the etiologic diagnosis can be made only by means of the culture method. For the examination of smears, van Loghem's Gram method gives the best results. Vulvovaginitis gonorrhoea occurs only in the acute form. Every case of vulvovaginitis gonorrhoea is complicated by gonorrhea of the rectum. In other forms of acute vulvovaginitis, hemolytic streptococci, influenza bacilli and diphtheria bacilli play a rôle. In chronic vulvovaginitis, probably the primary cause is a constitutional disease."

In our own¹⁰ study of vaginitis in the Washington University Dispensary, we have used the Gram stain for all specimens and have checked our findings by the culture method, using Gradwohl's⁹ media. The results showed that approximately 40 per cent of the children registered in our vaginitis clinic suffered from a specific gonorrheal infection. We have grouped the cases into specific and nonspecific vaginitis and have thereby reduced the total number of patients being treated for gonorrheal vaginitis to a very small group. The period of attendance for the nonspecific group has been greatly reduced. A positive diagnosis is made on demonstration of typical biscuit-shaped intracellular gram-negative diplococci on direct smear and culture of the organisms on the special hormone-agar media.

TREATMENT

Vaccines of many different types have been used with very little consistent relief being obtained in most cases.

Innumerable antiseptics have been used for many years, the favorites being members of the silver group. In 1920, Gellhorn¹¹ proposed the use of 1 or 2 per cent silver nitrate in an ointment base. The duration of the disease was not greatly shortened by this treatment and at times complete failures resulted. Potassium permanganate has been used extensively in varying concentrations and seems to be of value, provided that the solution is 1:2000 or stronger. A solution of 1:1000 in my experience has given excellent results without any harmful reaction in the tissues.

Schauffler⁵ in 1927 described his method of treatment by the use of an antiseptic incorporated in anhydrous wool fat as a base, and this antiseptic preparation was forced into the vagina under sufficient pressure to cause distention of the vagina and flattening of the rugae. In 1933, he reported with Kuhn³ on the use of this method in over 2000 treatments with satisfying improvement in a large series of stubborn cases, in the majority of which several other methods had failed. They considered the method harmless and effective.

In 1928, Edgar Allen¹² demonstrated the transformation that could be effected in the vagina of the immature monkey by the administration of ovarian hormone. After the injection of 1005 rat units of ovarian hormone over a period of twenty-one days, the vagina of the monkey exhibited an epithelium averaging 30 layers in thickness and differentiated into two zones. The vaginal epithelium of the control monkey, on the other hand, remained 4 to 8 layers in thickness. Smears showed a proportional increase of partly or completely cornified epithelial cells. Associated with the vaginal changes there was some development of the cervical glands and an invasion of their lumina by many polymorphonuclear leukocytes. The endometrium was "built up" at most to a midinterval phase. Involution of the structures affected by the hormone occurred in a few weeks subsequent to the last injection of the hormone.

Lewis² asked, "Could a similar result be obtained in a child? A gonococcal infection in the vagina subsides when the delicate thin layered epithelium lining the vagina is converted into the thicker structure of the adult. Primary infection in the adult vagina is either extremely shortlived or nonexistent."

With these ideas in mind Lewis² began the study of the effect of theelin on gonorrheal vaginitis in children and in 1933 reported his results in a series of 8 cases. Subsequent to this several reports have been made showing the good results obtained by the administration of hormone therapy in varying doses by different routes.^{13, 14, 15}

Witherspoon¹ reported that 10 children with gonorrheal vulvovaginitis have been unsuccessfully treated by the administration of the ovarian follicular hormone, amniotin. The criteria of lack of success are the persistence of the vaginal discharge and the presence of gram-negative intracellular diplococci in the vaginal smears. Several disadvantages of this method of therapy are pointed out, such as the harmful effect on the immature ovary by the hormonal action on it, cervical infection in addition to vaginitis as a focus of continuing the disease, the unpleasant features of the daily hypodermic injections, the occasional unfortunate secondary sexual changes, such as enlargement of the breasts, vulval hyperemia and hypertrophy, and lastly the high cost of this method of therapy.

It is very likely that the observations of Witherspoon are the result of inadequate dosage or because of the manner in which the hormone was administered.

Allen and Diddle¹⁶ have checked the ovarian follicular hormone effects on the ovaries in an experimental way, using immature monkeys. There was definite reddening and swelling of the sexual skin and an increase in the size of the uterus was noted. The ovaries were studied immediately after the period of injection and also after a thirty-day recovery period. They concluded, as far as they could tell histologically, that there seemed to be little damage to the ovaries, and that the reaction was temporary. They state, "The therapeutic use

of comparable doses of this hormone in children may be prescribed without fear of harmful results upon the ovaries."

TeLinde and Brawner¹⁷ conclude: "Amniotin administered orally or hypodermically in ethylene glycol solution is of no value in the treatment of gonococcal vaginitis. We have been unable to demonstrate any effect of the hormone on the vaginal mucosa or breasts. Amniotin in oil has proved effective both in the production of maturation of the vaginal mucosa and in its therapeutic action in gonococcal vaginitis in 72 per cent of the cases. In most of the patients receiving prolonged treatment breast hypertrophy was noted. Amniotin in suppository form has been proved to be effective in the production of mature vaginal epithelium and in its therapeutic effect in gonococcal vaginitis in all cases in which we have used it. This group included some cases which had been resistant to the hormone when administered hypodermically in oil. The epithelial change produced by the hormone, whether administered hypodermically or in suppositories, is transient, and there is no clinical or experimental evidence to show that its administration is harmful in dosage necessary to cure this disease. So far as our experience has gone we have concluded that amniotin administered in suppository form is superior to any other known method of treating gonococcal vaginitis."

Lewis and Adler¹⁸ found that the estrogenic substance in ethylene glycol given hypodermically was relatively effective when used in large doses: 2400 International units daily. Eight hundred International units daily proved disappointing. Estrogenic vaginal suppositories (originally 600 International units and later 1000) proved very effective. They also noted that the administration of estrogenic substance changes the reaction of the vaginal secretions from neutral or alkaline to acid, and believe this to be a major factor in elimination of the gonococcal infection. The acidity of the vaginal secretions is easily measured and provides a sure guide by which one can determine whether or not dosage is adequate. They encountered no ill effects and consider this type of therapy harmless and also most effective.

Marion and Magnan¹⁰ made a preliminary report on the treatment of vaginitis with: (1) a pyridium solution douche, (2) insertion of pyridium suppositories, (3) oral administration of pyridium tablets. Details of their cases and the percentage of pyridium in the suppositories were not noted in their paper.

In 1934, we¹⁰ reported a three-year study of the treatment of gonorrheal vaginitis by the insertion of vaginal suppositories containing 0.16 Gm. pyridium in a base of boroglyceride of gelatin, at bed time. This is followed by a cleansing douche of 1:1500 potassium permanganate (5 grains to 1 pint of water). It was possible to obtain negative smears and cultures in definite cases of gonorrheal vaginitis following the treatment by the suppositories alone. We have now studied about 50 cases of gonorrheal vaginitis treated satisfactorily by this method and feel that it is definitely effective, simple in application and has no harmful side actions. The average course of treatment extended over a period of from four to eight weeks, depending upon the cooperation of the patient in carrying out the treatment. Treatment should probably be continued for ten days to two weeks after negative smears are obtained. By means of this type of treatment any complicating urethral infection is taken care of by the fact that pyridium is absorbed from the vagina and is excreted through the urinary tract, bathing the urethra with a definitely antiseptic solution. The folds, as noted in the vaginal portion of the cervix by Schauffler,⁵ are also treated by this method of application and it seems likely that reinfection of our cases has been less frequent than in other series because of these additional actions. The *pH* of the pyridium suppositories is approximately 4.0 and it is possible that this chemical reaction in the vagina enhances the action of the pyridium suppositories. The importance of the *pH* of the vagina will be stressed in the consideration of other methods of therapy.

Abrams²⁰ reports his impressions of the various types of therapy and finds, "A small percentage of the patients in the past who have had persistent positive smears have shown in-

volvement of the cervical glands. I feel that in a large series of cases it is possible this will occur even with the use of estrogenic substance and when smears do not become negative the cervix should be investigated by means of a small electrically lighted endoscope."

Crossen²¹ reported on the treatment of gonorrheal vaginitis by diathermy and obtained consistently negative smears after twenty-nine weeks in the acute series. The average length of treatment required to give consistently negative smears in the chronic cases was a little over four weeks. The difficulties in applying this method of treatment to young children make it undesirable from a practical standpoint.

Notes,²² discussing the routine treatment of gonorrhea in females, took a very definite stand against the antiseptic method of treatment, based upon his observations at the City Social Hygiene Clinic of the District of Columbia. He expressed the belief that the best method of treatment was to establish and maintain drainage of the various foci of infection encountered in the female tract. The creation of a local reaction and drainage was his final method of treatment in his clinic, and as a result a much larger number of patients were discharged from the clinic. Electrocautery was applied to the cervical glands at intervals of two months and 25 per cent silver nitrate solution was applied as a local irritant to the urethral meatus and cervix weekly. One drachm of 1 per cent lactic acid jelly was applied to the vaginal vault nightly in an attempt to establish a normal bacterial flora.

It is my practice in the treatment of adults with chronic gonorrhea on the Gynecological Service at the St. Louis City Hospital, to attempt the removal of foci of infection by: (1) coagulation of Skene's glands and (2) conization of the cervix. Joachimovits²³ in his book on gonorrhea of the female genital tract, highly recommends the Sturmdorf operation as a means of removal of local foci. Such a procedure is simplified by the use of the operation of conization with the Crossen electrode. A word of caution must be introduced to warn against the use of even superficial cautery in treatment in the acute stage, as

we have seen cases of severe pelvic peritonitis develop therefrom.

Karnaky²¹ has studied the treatment of vaginitis in general in regard to: (1) the bacterial flora of the vagina, (2) the glycogen content of the vaginal mucous membrane, (3) the number of Döderlein bacilli present, (4) pathological conditions of the vagina, and (5) the hydrogen ion concentration of the vaginal secretions. He finds that there is a definite relationship between these five factors upon which depends the life and growth of vaginal micro-organisms. As a result of his study, he recommends a tablet containing an adequate amount of glucose in a form that can be utilized to supply the epithelial cells and nourish the Döderlein bacillus. Sufficient boric acid is added to establish a pH of 4.0 and produce a mild astringent action thus diminishing the amount of the discharge. Also incorporated in the formula is a quantity of "Diodoquin," a new quinoline ring giving it an iodine content of 63 per cent (5-7 Diiodo-8-Hydroxyquinoline). It is an insoluble and non-toxic compound and experiments which he has conducted prove its effectiveness in destroying organisms of the protozoan type. His treatment has also proved satisfactory in the treatment of gonorrheal vaginitis. The name of the preparation used is "Floradex." A very interesting diagram is shown, illustrating the life cycle of the vaginal epithelium, in which one sees the change in pH that occurs shortly after birth and remains until puberty, thereby allowing a definite change to occur in the vaginal flora of a child. He also illustrates the drop in pH during pregnancy when there is a marked increase in the presence of estrogenic substances in the blood stream of the mother and the epithelial layer of the vagina is greatly thickened. This latter factor may be of the utmost importance in the clearing up of a gonorrheal vaginitis as pregnancy proceeds to term.

In the Washington University Dispensary the treatment of gonorrheal vaginitis complicating pregnancy has been by means of potassium permanganate douches 1:1500 throughout the pregnancy, with the result that no gonococci could be demon-

strated in the genital tract of these cases at term. There have been no maternal or fetal complications in these cases.

The importance of the pH of the vaginal secretions in relation to the cure of gonorrheal vaginitis will now be considered. Lewis and Adler¹⁸ stress this factor as the means of demonstrating adequate estrogenic therapy. They state, "It is of course of the utmost importance to determine the presence or absence of the vaginal response to estrogenic substance in all cases, as without this tissue change no benefit can be expected. This was formerly done by securing minute biopsies and examining sections with the aid of the microscope. This method is time consuming and expensive. Vaginal smears showing extraordinary desquamation of epithelial cells are evidence that the estrogenic reaction has occurred. The inexperienced observer will, however, often be misled, particularly if the exfoliation is not great. The gross appearance of the vaginal mucosa and introitus is frequently helpful. We wish now to stress the value of another simple practical test of the estral response which can be carried out easily in a few minutes. Long ago Döderlein²⁵ called attention to the presence of the bacillus named for him and considered its acid-forming properties as responsible for the acid reaction of the secretions of the adult female vagina. Zweifel²⁶ later showed that it was the destruction of the superficial glycogen containing cells of the vaginal mucosa that produces much of the acidity. In the thin vaginal mucosa of the child but little glycogen is contained. On the other hand, the superficial cells of the adult vagina and, of more importance to us, of the vagina of the child adequately treated with estrogenic substance are loaded with glycogen. These as a result of bacterial or enzymatic action produce a markedly acid reaction as they break down. Soeken,²⁷ Cruickshank²⁸ and others have described the histologic changes that occur during puberty and ordinarily before the occurrence of the first menstrual period. They have also pointed out the dramatic and abrupt change to acidity in reaction of the vaginal secretion which occurs at this time and that this in turn is accompanied by an equally rapid transformation of the vag-

inal flora. *In vitro* the gonococcus grows best in a faintly alkaline medium (pH 7.2 to 7.6). If this is rendered acid very gradually over a period of days or weeks these organisms will rarely adapt themselves to a medium as acid as pH 6 to 6.2. Usually the culture dies before this point is reached. Tests that we have carried out to determine the pH of the vaginal secretions of children in our series before treatment have given pH values between 6.8 and 7.4. With the appearance of the estrogenic reaction of the vaginal mucosa (checked by biopsy and microscopic section), the vaginal secretions became acid (pH 4.5 to 6.2), nearly always giving readings below 6. Nearly every case in which the pH of the vaginal secretions dropped to below 6 recovered from the gonococcic infection. Consequently we believe this acid change of the vaginal secretion is the important curative factor produced by administration of estrogenic substance in gonococcic vaginitis of children."

Krumm²⁹ finds variations in the glycogen content of the vaginal mucosa as shown by the Schiller-Gram test to be a relative index to the quantitative amount of ovarian hormone present in the body. This test can, therefore, be used in checking the efficacy of estrogenic substances which have been given by various methods in the hope of obtaining a therapeutic response.

Adair and Hesseltine³⁰ have investigated the histopathology of vaginitis and the biochemical approach to therapy thereof. A mixture of lactose (95 per cent) and citric acid (5 per cent) was used with the result that definite changes occurred in the epithelial layers of the vaginal wall. The histological picture is restored to nearly normal including an increase in the number of glycogen granules in the epithelial cells. The use of lactose instead of glucose as the sugar in such treatment is emphasized in order that the development of mycosis may be avoided.

Oberst and Plass³¹ studied the hydrogen ion concentration of human vaginal discharge by means of a quinhydrone micro-electrode and found it to be normally pH 4 to 4.5 during the intermenstrual period. They also noted the corresponding

changes in the vaginal flora that occur with the changes in reaction.

We see, therefore, that a number of biochemical, endocrinological and histopathological factors must be taken into account if our therapy of gonorrheal vaginitis is to be rational.

CONCLUSIONS

1. Vaccines as yet have offered little aid.
2. In general the results of antiseptic treatment have been disappointing.
3. "Floradex" is apparently a rational therapeutic agent, but might be improved by the substitution of lactose for the dextrose used.
4. Hormone therapy is successful if the estrogenic substance is given by the proper route (as suppositories) in adequate dosage. There is apparently an appreciable number of recurrences. May these not be due: (a) to the development of cervical and endometrial glands, in response to the estrogenic substance (Allen¹²), which would predispose to the spread of the infection to areas which have not been involved in the original disease and upon the withdrawal of treatment these areas might act as foci and reinfect the vagina as it returns to its original immature state; (b) to the lack of treatment of certain original foci (*e. g.*, urethritis)?
5. We may still be unaware of certain by-effects of hormonal treatment which have not been demonstrated as yet, but may nevertheless be present and cause possible complications in certain patients at a later period in their development.
6. Pyridium therapy has been generally satisfactory in both specific and nonspecific vaginitis. It is (a) quite economical, (b) prompt in production of results, (c) easy of application, and (d) general in action as well as local, which may account for the lesser incidence of recurrences.
7. Progress in the treatment of gonorrheal vaginitis will be made if we continue to rationalize our therapy along biochemical and endocrinological lines. Perhaps the best results

can be obtained in certain cases by the use of various combinations of the methods discussed.

CUMULATIVE INDEX

- ABDOMINAL diseases causing fever in children, *July*, 21
 Abortion, diagnostic mistakes, *July*, 76
 habitual, *July*, 81, 93
 Abscess, abdominal, in children, *July*, 26
 mediastinal, in children, *July*, 18
 of brain in children, *July*, 43
 of breast, acute, *Sept.*, 627
 chronic, *Sept.*, 630
 of kidney, multiple, in children, *July*, 33
 of lung, multiple, in children, *July*, 18
 pulmonary bleeding in, *Sept.*, 486
 perinephric, in children, *July*, 33
 retropharyngeal, in children, *July*, 13
 subphrenic, in children, *July*, 26
 Acromegaly, *Sept.*, 387
 Addison's disease, borderline cases, *Sept.*, 345
 Adenoids, infected, fever due to, *July*, 10
 Adiposis dolorosa, *Sept.*, 374
 Adiposity, cerebral, *Sept.*, 374
 Adiposogenital dystrophy, *Sept.*, 374
 Adrenal cortical tumors, *Sept.*, 349
 insufficiency, borderline cases, *Sept.*, 345
 Allergic asthma, treatment, *Sept.*, 591
 infants, colic in, *Sept.*, 512
 Alternation of heart, *July*, 188; *Sept.*, 545
 Amebic dysentery in children, *July*, 24
 Anal obstruction in newborn, *Sept.*, 622
 Anemia and hypothyroidism, *Sept.*, 340
 sickle cell, *July*, 55
 Appendicitis, acute, in aged, *July*, 133
 in children, fever in, *July*, 25
 Arcus senilis, *July*, 128
 Arrhythmias, diagnosis and treatment, *July*, 175
 significance of, *Sept.*, 537
 Arsenic encephalitis, *Sept.*, 417
 Arteriosclerosis in cardiovascular-renal disease, *July*, 209
 Arthritis, gonorrheal, in male, *July*, 152
 Asphyxia neonatorum, *July*, 99
 Aspiration in pleurisy, *July*, 329
 Associated movements, automatic, abnormal, *July*, 227
 Asthenia, neurocirculatory, simulating hyperthyroidism, *Sept.*, 343
 Asthma, bronchial, treatment, *Sept.*, 591
 emphysema in, *Sept.*, 443
 Atelectasis, pulmonary, in newborn, *July*, 106, 111
 Ateliosis, *Sept.*, 362
 Atopy, *Sept.*, 652
 Auricular fibrillation, *July*, 181; *Sept.*, 541
 flutter, *July*, 184; *Sept.*, 541
 Auriculoventricular block, *Sept.*, 544
 Australian X disease, *Sept.*, 424
 Autohemotherapy in herpes zoster, *July*, 245
 Autonomic imbalance in newborn, *Sept.*, 623
 BASOPHILISM, pituitary, *Sept.*, 349, 387
 Beet pulp, laxative value, *Sept.*, 457
 Birth trauma, vomiting due to, *Sept.*, 623
 Blepharospasm in parkinsonism, *July*, 228
 Blood, disorders, genetic aspects, *July*, 253
 pulmonary bleeding in, *Sept.*, 490
 iodine, in hyperthyroidism, *July*, 286
 vessels, diseases of, pulmonary bleeding in, *Sept.*, 489
 Bones, diseases, in aged, *July*, 138
 Botulism, *July*, 265
 in children, *July*, 28
 Brain abscess in children, *July*, 43
 tumors in children, *July*, 47
 Breast, diseases of, differential diagnosis, *Sept.*, 625
 Brill's disease, *July*, 52
 Bronchi, diseases of, causing bleeding, *Sept.*, 485
 Bronchial asthma, treatment, *Sept.*, 591
 Bronchiectasis as cause of fever in children, *July*, 18
 pulmonary bleeding in, *Sept.*, 485

- Bronchitis, chronic, emphysema in, *Sept.*, 443
 in aged, *July*, 135
 Broncholithiasis, pulmonary bleeding in, *Sept.*, 486
 Bronchopulmonary bleeding, diagnosis and treatment, *Sept.*, 483
 Bronchoscopy in pulmonary hemorrhage, *Sept.*, 492
Brucella melitensis, *July*, 51
 Bulky foods, laxative value, *Sept.*, 449

 CARUNCLE of kidney in children, *July*, 33
 Carcinoma of breast, *Sept.*, 641, 642
 of cervix, diagnostic mistakes in, *July*, 78
 of lung, pulmonary bleeding in, *Sept.*, 487
 Cardiac. See *Heart*.
 Cardiovascular disease in aged, *July*, 139
 physical exercise in, *July*, 191
 Cardiovascular-renal disease, preventive aspects, *July*, 209
 Cellulose in foods, *Sept.*, 450
 Cereals, thick, feeding of, in gastroenterospasm, *Sept.*, 518, 519
 Cerebral adiposity, *Sept.*, 374
 edema and hemorrhage in newborn, *July*, 105, 109
 Cervical lymphadenitis in children, *July*, 14
 Cervix, carcinoma of, diagnostic mistakes, *July*, 78
 Chickenpox, encephalitis in, *Sept.*, 433
 Cholecystitis, acute, diagnosis, *Sept.*, 472
 chronic, diagnosis, *Sept.*, 473
 Cholecystography, intravenous, *Sept.*, 475
 oral, *Sept.*, 478
 Cholesterosis, *Sept.*, 473
 Cogwheel motor rigidity, *July*, 232
 Colds, common, as cause of fever in children, *July*, 9
 Colic, infantile, classification and treatment, *Sept.*, 511
 Colitis, ulcerative, in children, *July*, 24
 Constipation and hypothyroidism, *Sept.*, 340
 bulky foods in, *Sept.*, 449
 Contact dermatitis, *Sept.*, 651, 653
 Contractions of heart, premature, *July*, 177
 Convulsions, uremic, treatment, *Sept.*, 532
 Corpus spongiosum, marked induration, in gonorrhea, *July*, 155
 Cosmetics and eczema, *Sept.*, 661

 Cowperitis, gonorrheal, *July*, 155
 Cramps and hypothyroidism, *Sept.*, 340
 Cretinism, *Sept.*, 355
 Cyanosis of newborn, diagnosis and treatment, *July*, 99
 Cystic mastitis, chronic, *Sept.*, 637
 Cystitis in children, *July*, 34

 DEFECATION, influence of indigestible residue on, *Sept.*, 453
 Dehydration fever in children, *July*, 47
 Dercum's syndrome, *Sept.*, 374
 Dermatitis, contact, *Sept.*, 651, 653
 Diabetes mellitus, borderline, *Sept.*, 346
 with hypothyroidism, *July*, 279
 Diaphragmatic pleurisy in children, *July*, 18
 Diathesis, exudative, *Sept.*, 656
 Dick antitoxin, *July*, 314
 test, *July*, 312
 toxin, *July*, 313
 Diet in cardiovascular-renal disease, *July*, 214
 in constipation, *Sept.*, 449
 in myocardial insufficiency, *Sept.*, 555
 in uremia, *Sept.*, 529
 Digestive tract diseases in aged, *July*, 132
 Digitalis in myocardial insufficiency, *Sept.*, 549
 Diuretics in myocardial insufficiency, *Sept.*, 553
 in uremia, *Sept.*, 530
 Diverticula, esophageal, in aged, *July*, 132
 Drugs causing fever in children, *July*, 45
 Duodenal obstruction in newborn, *Sept.*, 621
 Dwarfism, *Sept.*, 353
 hypothyroid, *Sept.*, 356
 Paltauf, *Sept.*, 362
 Dysentery, amebic, in children, *July*, 24
 bacillary, in children, *July*, 24
 Dyspituitarism, postencephalitic, *July*, 229
 Dystonia, neurovegetative, *July*, 233
 Dystrophia adiposogenitalis, *Sept.*, 374

 ECTOPIC pregnancy, *July*, 77
 Eczema, *Sept.*, 651
 Eczematids, *Sept.*, 654
 Edema, cerebral, in newborn, *July*, 105, 109

- Emphysema, early diagnosis and treatment, *Sept.*, 437
- Empyema, *July*, 329
- encapsulated, in children, *July*, 18
- Encephalitis, clinical types, diagnosis and treatment, *Sept.*, 415
- epidemic, *Sept.*, 419
- dyspituitarism following, *July*, 229
- parkinsonism following, diagnosis and treatment, *July*, 223
- in children, *July*, 39
- toxic, *Sept.*, 415
- postvaccinal, *Sept.*, 430
- Encephalomyelitis, acute disseminated, associated with infections, *Sept.*, 430
- Endocarditis, subacute bacterial, in children, *July*, 57
- Endocervicitis, chronic, treatment, *July*, 119
- Endocrine disturbances, borderline, *Sept.*, 337
- in aged, *July*, 138
- infantilism, diagnosis and treatment, *Sept.*, 353
- obesity, *Sept.*, 369
- symposium, *Sept.*, 335
- Enterospasm, infantile, classification and treatment, *Sept.*, 511
- Enuresis and hypothyroidism, *Sept.*, 339
- Epididymitis, gonorrheal, *July*, 150
- Erysipelas in aged, *July*, 137
- Esophagus, obstruction, in newborn, *Sept.*, 617
- pressure, diverticula, in aged, *July*, 132
- Estrogenic hormone therapy in gonorrheal vaginitis, *Sept.*, 669, 675
- Exanthem subitum, *July*, 48
- Exercise in cardiac conditions, *July*, 191
- Exophthalmic goiter, *July*, 285
- Extrasystoles, *July*, 177; *Sept.*, 540
- Exudative diathesis, *Sept.*, 656
- FAINTING, attacks and hypothyroidism, *Sept.*, 339
- Feeding, infant, in relation to vomiting in newborn, *Sept.*, 616
- Fever in childhood, obscure origin, symposium on, *July*, 1
- Fibro-adenoma of breast, *Sept.*, 633
- Fibromyxoma of breast, *Sept.*, 636
- loralex in gonorrheal vaginitis, *Sept.*, 674
- folliculitis, gonorrheal, *July*, 153
- food poisoning in children, *July*, 27
- Food residue, indigestible, influence on defecation, *Sept.*, 453
- method of isolating, *Sept.*, 450
- necessity in diet, *Sept.*, 455
- Foods, bulky, laxative value, *Sept.*, 449
- Foreign body in lung, pulmonary bleeding in, *Sept.*, 488
- Fractures in aged, *July*, 138
- Fröhlich's syndrome, *Sept.*, 374
- Functional disorders of children, diagnosis and treatment, *Sept.*, 581
- Fungus infections of lung, pulmonary bleeding in, *Sept.*, 488
- Fusospirochetosis of lung, pulmonary bleeding in, *Sept.*, 488
- GALLBLADDER, stoneless, diagnosis, *Sept.*, 471
- strawberry, *Sept.*, 473
- Gallstones in aged, *July*, 134
- Gangrene of lung, pulmonary bleeding in, *Sept.*, 487
- Gastro-enterospasm, infantile, classification and treatment, *Sept.*, 511
- Gastro-intestinal obstruction as cause of vomiting in newborn, *Sept.*, 617
- Genetic aspects of certain blood-system disorders, *Sept.*, 253
- Genito-urinary system, diseases, in aged, *July*, 134
- Geriatrics, *July*, 127
- German measles, encephalitis in, *Sept.*, 433
- Gigantism, *Sept.*, 387
- Glandular fever in children, *July*, 55
- Goiter, toxic, *July*, 285
- Gonorrhea in male, complications, treatment, *July*, 147
- Gonorrheal arthritis, *July*, 152
- prostatitis, *July*, 150, 161
- vulvovaginitis, *July*, 123; *Sept.*, 665
- Graves' disease, *July*, 285
- Grippe, intestinal, *July*, 26
- Growth hormone therapy, *Sept.*, 365
- Gynecology, diagnostic mistakes, *July*, 75
- problems of family physician, symposium on, *July*, 59
- HABIT vomiting in newborn, *Sept.*, 624
- Heart, alternation of, *July*, 188; *Sept.*, 545
- block, *July*, 185
- and hypothyroidism, *Sept.*, 339
- disease, in aged, *July*, 139
- pulmonary bleeding in, *Sept.*, 489
- physical exercise in, *July*, 191
- with cyanosis in newborn, *July*, 105, 111

- Heart, irregularities, diagnosis and treatment, *July*, 175
 significance, *Sept.*, 537
 premature contractions, *July*, 177
 Hemicellulose in foods, *Sept.*, 450
 Hemoglobinuria, paroxysmal, *July*, 56
 Hemophilia, *July*, 258
 Hemoptysis, diagnosis and treatment, *Sept.*, 483
 Hemorrhage, cerebral, in newborn, *July*, 105, 109
 pulmonary, diagnosis and treatment, *Sept.*, 483
 Herpes zoster, treatment, *July*, 239
 Hodgkin's disease in children, *July*, 54
 Hormone therapy in gonorrheal vaginitis, *Sept.*, 669, 675
 in habitual abortion, *July*, 96
 in hypopituitarism, *Sept.*, 384
 in infantilism, *Sept.*, 360, 364, 365
 in sterility, *July*, 70
 Hyperinsulinism, diagnosis and treatment, *Sept.*, 393
 Hyperpituitarism, treatment, *Sept.*, 386
 Hypertension in cardiovascular-renal disease, *July*, 209
 Hyperthyroidism, *July*, 285
 borderline cases, *Sept.*, 342
 with normal metabolic rate, *Sept.*, 344
 Hypoglycemia of hyperinsulinism, *Sept.*, 393, 402
 differentiation from other states of hypoglycemia, *Sept.*, 404
 spontaneous, *Sept.*, 347
 Hypogonadism, primary, *July*, 68
 Hypopituitarism, treatment, *Sept.*, 379
 Hypothyroid infantilism, *Sept.*, 356
 Hypothyroidism, borderline cases, *Sept.*, 337
 in diabetes mellitus, *July*, 279
 ICTERO-ANEMIA, hemolytic, genetic aspects, *July*, 256
 Impedance angle in hyperthyroidism, *July*, 287
 Infantile colic, classification and treatment, *Sept.*, 511
 Infantilism, endocrine, diagnosis and treatment, *Sept.*, 353
 Infections, acute, in aged, *July*, 137
 encephalitis following, *Sept.*, 430
 in newborn, vomiting due to, *Sept.*, 622
 Inflammatory diseases of breast, *Sept.*, 627
 pelvic, ectopic pregnancy and, differentiation, *July*, 77
 Influenza, encephalitis following, *Sept.*, 437
 in children, fever in, *July*, 18
 Inguinal lymphadenitis in gonorrhea in male, *July*, 156
 Injuries of lung, pulmonary bleeding in, *Sept.*, 487
 Intestinal grippe, *July*, 26
 obstruction in aged, *July*, 133
 tuberculosis in children, *July*, 21
 Iodine, blood, in hyperthyroidism, *July*, 286
 Irritability and hypothyroidism, *Sept.*, 339
 JAPANESE type B encephalitis, *Sept.*, 423
 Jaundice, epidemic, in children, *July*, 29
 KIDNEY, abscesses, multiple, in children, *July*, 33
 carbuncle, in children, *July*, 33
 tuberculosis, in children, *July*, 34
 tumors, in children, *July*, 34
 LEAD encephalitis, *Sept.*, 417
 Leukemia in children, *July*, 54
 Lethargic encephalitis, *Sept.*, 419
 Lignin in foods, *Sept.*, 450
 Lipomatosis, *Sept.*, 378
 Liver, enlargement, diseases associated with, diagnosis, *July*, 295
 Lobectomy in pulmonary hemorrhage, *Sept.*, 492
 Lorain-Levi infantilism, *Sept.*, 362
 Lung, abscesses, multiple, in children, *July*, 18
 hemorrhage from, diagnosis and treatment, *Sept.*, 483
 diseases, in aged, *July*, 135
 Luxus consumption, *Sept.*, 365
 Lymph nodes, mesenteric, tuberculosis of, *July*, 22
 Lymphadenitis, cervical, as cause of fever in children, *July*, 14
 inguinal, in gonorrhea in male, *July*, 156
 Lymphangitis, gonorrheal, in male, *July*, 156
 MALARIA in children, *July*, 53
 inoculata, *July*, 53
 Malpositions of uterus, diagnostic mistakes, *July*, 79
 Malta fever, *July*, 51

- Mastitis, cystic, chronic, *Sept.*, 637,
 641
 pyogenic, acute, *Sept.*, 627
 chronic, *Sept.*, 630
 tuberculous, *Sept.*, 630
 Mastoiditis as cause of fever, *July*, 15
 Measles, encephalitis in, *Sept.*, 432
 Mediastinal abscess in children, *July*,
 19
 infection, as cause of fever in chil-
 dren, *July*, 18
 Meningitis, acute aseptic, *July*, 41
 lymphocytic, *July*, 40
 serous, *Sept.*, 438
 meningococcic, *July*, 35
 miscellaneous forms, *July*, 38
 syphilitic, *July*, 42
 tuberculous, *July*, 37
 Menopause, abnormal bleeding before
 and after, causes, *July*, 83
 Menstruation, vicarious, from lungs,
 Sept., 490
 Mesenteric lymph nodes, tuberculosis
 of, *July*, 22
 Metabolism, basal, in hyperthyroid-
 ism, *July*, 288
 Miscarriage, diagnostic mistakes in,
 July, 76
 persistent, *July*, 81
 Mönckeberg's sclerosis, *July*, 130
 Mononucleosis, acute infectious, *July*,
 55
 Morbus coeruleus, *July*, 106
 Mumps, encephalitis in, *Sept.*, 436
 Muscular pains and hypothyroidism,
 Sept., 340
 Myocardial insufficiency, treatment,
 Sept., 547
 Myxoma, intracanalicular, of breast,
 Sept., 636

 NANOSOMIA hypothyrotica, *Sept.*, 361
 Nasal septum, ulcer of, and hypothy-
 roidism, *Sept.*, 338
 Neoarsphenamine in herpes zoster,
 July, 248
 Nephrosclerosis in aged, *July*, 134
 Neurocirculatory asthenia simulating
 hyperthyroidism, *Sept.*, 343
 Neuroses from general practitioner's
 viewpoint, *Sept.*, 559
 Newborn, cyanosis of, *July*, 99
 sepsis of, *July*, 47
 vomiting in, *Sept.*, 615

 OBESITY and hypothyroidism, *Sept.*,
 339
 endocrine, *Sept.*, 369
 exogenous, *Sept.*, 376

 Obstetric problem of family physician,
 symposium on, *July*, 59
 Occupational therapy in myocardial
 insufficiency, *Sept.*, 557
 Oculogyric crises, *July*, 228; *Sept.*, 422
 Oertel terrain exercises, *July*, 203
 Old age, diseases of, *July*, 127, 131
 Ornsteen's triad, *July*, 234
 Osteomyelitis in children, *July*, 49
 Otitis media, fever due to, *July*, 15
 Ovalocytosis, *July*, 257
 Ovarian failure, primary, *July*, 68

 PAGET's disease in aged, *July*, 138
 Paltauf dwarfism, *Sept.*, 362
 Pancreatitis, acute, in children, *July*,
 26
 Parafrenal sinusitis in gonorrhea, *July*,
 158
 Paraphimosis, gonorrheal, *July*, 157
 Paratyphoid fever in children, *July*, 23
 Parkinsonism, *Sept.*, 422
 incipient, diagnosis and treatment,
 July, 223
 Paroxysmal tachycardia, *Sept.*, 544
 Parrot fever, *July*, 56
 Pastia's sign, *July*, 309
 Patch tests in eczema, *Sept.*, 659
 Pel-Ebstein Hodgkin's disease, *July*
 54
 Pelvic inflammatory disease, ectopic
 pregnancy and, differentiation, *July*,
 77
 Peptic ulcer, *Sept.*, 461
 Perinephric abscess in children, *July*,
 33
 Peritonitis in children, fever in, *July*,
 25
 tuberculous, in children, *July*, 22
 Pertussis, encephalitis in, *Sept.*, 436
 Phenobarbital in infantile colic, *Sept.*,
 517, 522
 Phimosis, inflammatory, in gonorrhea,
 July, 156
 Phlebitis, dorsal, gonorrheal, *July*, 156
 Phrenic nerve injury in newborn, *July*,
 105, 110
 Phyone, *Sept.*, 360, 364, 384
 Physical exercise in cardiac conditions,
 July, 191
 Pill-rolling tremor, *July*, 232
 Pituitary basophilism, *Sept.*, 349, 387
 hyperfunction, treatment, *Sept.*, 379
 infantilism, *Sept.*, 362
 insufficiency in sterility, *July*, 67
 treatment, *Sept.*, 379
 Pituitrin in herpes zoster, *July*, 246
 Pleurisy, acute, treatment, *July*, 323
 diaphragmatic, in children, *July*,
 18

- Pneumococcosis, pulmonary bleeding in, *Sept.*, 488
 Pneumonectomy in pulmonary hemorrhage, *Sept.*, 492
 Pneumonia in aged, *July*, 136
 in children, fever in, *July*, 17
 pulmonary bleeding in, *Sept.*, 488
 Pneumothorax, artificial, in pulmonary hemorrhage, *Sept.*, 492
 Poliomyelitis, *July*, 38
 Postmenopausal bleeding, causes, *July* 88
 Postural emphysema, *Sept.*, 442
 Pregnancy, and hypertension, *July*, 221
 ectopic, pelvic inflammatory disease and, differentiation, *July*, 77
 Premenopausal bleeding, causes, *July*, 85
 Prephysis, *Sept.*, 386
 Prostatic hypertrophy, *July*, 135
 Prostatitis, chronic, management, *July*, 161
 foci of infection in, *July*, 168
 gonorrheal, *July*, 150, 161
 Pruritus in uremia, treatment, *Sept.*, 533
 Psittacosis, *July*, 56
 Psychoses from general practitioner's viewpoint, *Sept.*, 559
 in aged, *July*, 140
 Pulsus alternans, *July*, 188
 Purpura in children, *July*, 57
 Pyelitis in children, fever due to, *July*, 31
 Pyloric obstruction in newborn, *Sept.*, 618
 Pyridium therapy in gonorrheal vaginitis, *Sept.*, 672
 Pyuria in children, fever due to, *July*, 31

 RABIES inoculations, encephalitis following, *Sept.*, 435
 Rat-bite fever, *July*, 52
 Relapsing fever, *July*, 53
 Renal-cardiovascular disease, preventive aspects, *July*, 209
 Respiratory disorders in parkinsonism, *July*, 229
 infections, encephalitis following, *Sept.*, 437
 lower, in children, fever due to, *July*, 17
 upper, in children, fever due to, *July*, 9
 Retropharyngeal abscess as cause of fever in children, *July*, 13
 Rheumatic fever in children, *July*, 27, 50
 Riedel's lobe, *July*, 299
 Rocky Mountain spotted fever, *July*, 52
 Roentgen diagnosis of silicosis, *Sept.*, 505
 of stoneless gallbladder, *Sept.*, 474
 treatment, of herpes zoster, *July*, 244
 Roseola infantum, *July*, 48
 Rumpel-Leede's sign, *July*, 309

 SCARLET FEVER, *July*, 307
 Schultz-Charlton reaction, *July*, 315
 Sclerosis, Mönckeberg's, *July*, 130
 Scurvy in children, *July*, 49
 Seminal vesiculitis in gonorrhea, *July*, 154
 Senescence, changes of, *July*, 128
 Sepsis of newborn, *July*, 47
 Sicklemia, *July*, 55
 genetic aspects, *July*, 258
 Silicosis, diagnosis and prevention *Sept.*, 497
 Simmonds' disease, *Sept.*, 383
 Sinus arrhythmia, *Sept.*, 540
 infection, paranasal, fever due to, *July*, 11
 Sinusitis, parafrenal, in gonorrhea, *July*, 158
 Smallpox, encephalitis in, *Sept.*, 433
 Sodium iodide in herpes zoster, *July*, 247
 Spherocytes, *July*, 256
 Splenomegaly, diseases associated with, diagnosis, *July*, 295
 St. Louis type encephalitis, *Sept.*, 424
 Stenosis, pyloric, in newborn, *Sept.*, 618
 Sterility in female, *July*, 63
 in male, *July*, 61
 Stokes-Oertel terrain exercises, *July*, 203
 Strawberry gallbladder, *Sept.*, 473
 Subphrenic abscess in children, *July*, 26
 Syphilitic meningitis in children, *July*, 42

 TACHYCARDIA, paroxysmal, *July*, 179; *Sept.*, 544
 Teeth, abscessed, in children, *July*, 48
 Teething, fever due to, *July*, 48
 Telangiectasia, hereditary hemorrhagic, *July*, 257
 Tetany in newborn, *July*, 112
 Thoracentesis in pleurisy, *July*, 328
 Thymus enlargement in newborn, *July*, 107, 111
 Thyroid eczema, *Sept.*, 657

- Thyrototoxicosis, hypoglycemia with, *Sept.*, 405
- Tonsils, infected, and fever, *July*, 10
- Trauma in production of eczema, *Sept.*, 653
- Tremor, pill-rolling, *July*, 232
- Trichomonas vaginalis vaginitis, treatment, *July*, 125
- Tuberculosis, intestinal, in children, *July*, 21
- of kidney in children, *July*, 34
- of mesenteric lymph nodes, *July*, 22
- pulmonary, in aged, *July*, 136
- in children, *July*, 19
- pulmonary bleeding in, *Sept.*, 485
- Tuberculous mastitis, *Sept.*, 630
- meningitis in children, *July*, 37
- peritonitis in children, *July*, 22
- Tularemia, *July*, 51
- Tumors, adrenal cortical, *Sept.*, 349
- of brain in children, *July*, 46
- of breast, *Sept.*, 633
- of kidney in children, *July*, 34
- Typhoid fever in children, *July*, 23
- Typhus fever, *July*, 52
- ULCER of nasal septum and hypothyroidism, *Sept.*, 338
- peptic, *Sept.*, 461
- Undulant fever in children, *July*, 51
- Uremia, treatment, *Sept.*, 527
- Urethritis, gonorrheal, in male, *July*, 147
- Uterus, malpositions, diagnostic mistakes, *July*, 79
- VACCINATION, encephalitis following, *Sept.*, 430, 433
- Vaginal bleeding, abnormal, pre- and postmenopausal, causes, *July*, 83
- discharges, diagnosing, *July*, 80
- Vaginitis, gonorrheal, treatment, *July*, 123; *Sept.*, 665
- Vagotonia, hypoglycemia in, *Sept.*, 404
- Vascular disease, hypertensive, *July*, 209
- Vesiculitis, seminal, in gonorrhea, *July*, 154
- Vicarious menstruation from lungs, *Sept.*, 490
- Vomiting in newborn, *Sept.*, 615

SYMPOSIUM ON PULMONARY TUBERCULOSIS

The following clinics are included in this Symposium:

Oscar Auerbach: THE PATHOLOGY AND PATHOGENESIS OF PULMONARY TUBERCULOSIS.

Bela Schick: TUBERCULOSIS IN CHILDHOOD.

David Umar: CLINICAL FORMS OF PULMONARY TUBERCULOSIS: THEIR RECOGNITION AND TREATMENT.

David Reisner: HEMATOGENOUS TUBERCULOSIS OF THE LUNGS.

George G. Ornstein: MANAGEMENT OF FAR ADVANCED TUBERCULOSIS.

Arthur J. Greenberger and Monroe E. Greenberger: UROGENITAL TUBERCULOSIS ASSOCIATED WITH PULMONARY TUBERCULOSIS.

M. Kovnat: PREGNANCY AND TUBERCULOSIS.

I. G. Epstein: FLUOROSCOPY AND x -RAY IN PNEUMOTHORAX THERAPY.

S. Edward King: THE TREATMENT OF DIABETES COMPLICATED BY TUBERCULOSIS.

Ralph F. Harloe: TUBERCULOUS EMPYEMA.

Irving Gray and Irving Greenfield: GASTRO-INTESTINAL SYMPTOMS IN PULMONARY TUBERCULOSIS.

Pol N. Coryllos: A NEW CONCEPTION OF THE MECHANICS AND PHYSIOLOGY OF COUGH.

Milton A. Bridges: DIET PRESCRIPTION FOR THE TUBERCULOUS.

CLINIC OF DR. OSCAR AUERBACH

FROM THE DEPARTMENT OF PATHOLOGY, SEA VIEW HOSPITAL

THE PATHOLOGY AND PATHOGENESIS OF PULMONARY TUBERCULOSIS

IN recent years roentgenologic findings have added so much to our knowledge of tuberculosis that pathology must be re-evaluated.

Ranke¹ divided tuberculosis into three stages analogous to those of syphilis. He termed the primary complex the first stage; the period of generalization the second stage, and isolated organ tuberculosis the third stage. All stages are related to allergic phenomena: the first stage is tuberculosis in an uninfected body; the second is tuberculosis in an oversensitized body; and the third stage is tuberculosis in a relatively immune body.

The chief objection to this view is that, although the stages in syphilis are sharply differentiated chronologically and in distribution, and pathologically show the changes of a single original infection, the total disease picture in tuberculosis has never been demonstrated to result similarly from a single infection. Moreover, the origin of the third stage is still debatable. Undoubtedly many cases of isolated pulmonary tuberculosis do not pass through a stage of generalization, but arise as a result of an exogenous infection.

The Primary Complex.—The tuberculous infection which begins as a nodular formation at the site of its entry into the body, with a similar involvement of the regional lymph nodes, was designated by Ranke as the primary complex. In most

cases the primary complex runs a definite course with definite anatomical healing. The correspondence of the anatomical changes within the focus and its draining lymph nodes distinguishes the primary complex from reinfects. Remnants of the primary complex, so frequently found at postmortem, represent the oldest tuberculous changes in the body.

Site and Frequency.—It is generally agreed that about 80 per cent of foci are found in the lungs. Fewer foci are found in chronic pulmonary tuberculosis because of the presence of excavations. Long and careful search is often necessary in order to demonstrate the remnants of a primary complex. The incidence of extrapulmonary primary infections, as reported, is variable, the greatest number occurring in the gastro-intestinal tract. The incidence of primary intestinal tuberculosis varies from 1.8 per cent (Puhl)² to 32.7 per cent (Blacklock).³ One can rely upon calcified mesenteric lymph nodes, usually in the ileocecal region, as evidence of a healed intestinal primary complex. The intestinal primary infection is attributed to the bovine type of tubercle bacillus, which generally enters in the region of the terminal ileum. According to Huebschmann⁴ and Jaffe,⁵ a small ulcer in this region heals quickly without leaving a scar. Huebschmann believes, also, that the tubercle bacilli may pass through the wall into the mesenteric lymph nodes without causing disease in the intestines. It is not altogether correct to designate a calcified node as evidence of primary infection, for, as Jaffe has pointed out, nonspecific infection may result in calcification of the mesenteric nodes. In a few cases both primary pulmonary and primary intestinal tuberculosis are observed. Cases of primary tuberculosis of the skin, tonsils, and middle ear have also been described.

Pulmonary Primary Focus.—The pulmonary primary focus, as a rule, occurs in early childhood, the greatest number of recent foci being seen in the first three years of life. Huebschmann reports that 60 per cent of fresh foci occur up to the age of fifteen years.

Site.—The foci are present chiefly in the well aerated

portions of the lung. This is readily understood when one considers that the focus is the result of the aspiration of tubercle bacilli. Ghon⁶ and Puhl² found the foci more frequently in the upper lobes, whereas Kiiss,⁷ Hedren⁸ and Huebschmann⁴ found them more often in the lower lobes. We have never seen primary foci in the apical aspects of the upper lobes, but have found them chiefly in the lower parts of the lower lobes. The right lung contains the focus as frequently as does the left, these foci being chiefly in the subpleural region where there is thickening and retraction of the overlying pleura.

Number of Foci.—In most instances, there is a single focus, although there may be multiple foci in one or more lobes. These may occur simultaneously, or as reinfects soon after the formation of the original primary focus. (Huebschmann asks whether foci which occur after the original infection may be called primary lesions.) The determination as to whether multiple primary foci occur at one time or at different periods is possible only when the foci are fresh. When anatomical healing is complete, it is no longer possible to ascertain the age of the individual nodules.

Gross Appearance.—The size and appearance of the primary focus depends upon the stage of development in which it is found. It may vary from 1 mm. to 2 cm. In the later stages, encapsulation and contraction cause shrinking. The pulmonary focus always remains smaller than the draining lymph nodes—this discrepancy in size being more marked in early than in late stages.

The first stage of primary foci has been observed only rarely. Those authors who have described it saw a localized area of pneumonia. From the rarity with which this pneumonia is observed, there is no doubt that it rapidly undergoes caseation.

The earliest stage of the primary focus usually observed at autopsy is that of an irregularly demarcated area of caseation surrounded by a gray-white capsule. The lung tissue immediately encircling the nodule is pneumonic in character.

When the nodule lies just beneath the pleura a localized fibrinous pleuritis is seen. At this period, the size of the focus varies from 1 to 2 cm. and it is round or polygonal.

In subsequent stages, the focus is surrounded by a definite gray capsule and is well demarcated from surrounding lung tissue. The nodule is circular in outline, and the lung tissue surrounding it is well aerated and sometimes emphysematous.

Fig. 40.—Healed primary complex. The picture shows a calcified focus in the left upper lobe. The lymph nodes in the left superior and left inferior tracheobronchial zone show corresponding changes.

Calcium deposition occurs early in these foci. The first signs of this are seen after encapsulation has become distinct, and consist in fine white points within the caseation. This calcium deposition may continue until the entire focus is composed of a crumbly, white mass surrounded by a gray capsule. When cut with a knife the foci are gritty. The size of the focus now is 1 cm. or less (Fig. 40).

Microscopic Findings of the Primary Focus.—Ghon⁶ and Zarfl,⁷ who described the early appearance of the focus, found an alveolus-filling process. The alveoli contain an exudate composed of polymorphonuclear leukocytes, lymphocytes, fibrin, and alveolar phagocytes. Numerous acid-fast bacilli are present in this pneumonic zone.

The pneumonia rapidly undergoes necrosis and it is usually in this stage of development that the early primary focus is first observed at autopsy. Swollen fibrin, necrotic nuclear remnants, intact polymorphonuclear leukocytes, and lymphocytes, are often seen in the early stages of caseation. The elastic fibers of the alveolar septa, vessels and bronchioles remain intact within the necrotic zone and are demonstrable in the zone of caseation even after calcification and ossification have been established. The presence of intact elastic fibers of the alveolar septa within the caseation identifies the focus as an original area of caseous pneumonia. The elastic fibers are destroyed only when the granulation tissue invades the area of caseation. The area of necrosis is surrounded by a zone of avascular epithelioid cell and giant cell tissue, containing fibroblasts and collagen fibrils. The cells are disposed radially along the inner border and tangentially on the outer aspect. The epithelioid cells may be arranged in tubercle formation along the edge of the caseation.

Beyond this specific granulation tissue, the alveoli contain an exudate (perifocal inflammation), composed of serum, alveolar phagocytes and lymphocytes. The extent of the perifocal inflammation depends upon the size of the caseous focus which it surrounds. The microscopic picture corresponds to the irregularly demarcated area of caseation surrounded by the pneumonic zone observed on gross examination.

As the area ages, the collagen fibrils laid down by the epithelioid cells become thicker and more numerous. They become hyalinized so that a definite capsule is formed. As this hyalinized capsule progresses, there is a simultaneous diminution of the epithelioid and giant cells owing to compression by collagen fibrils. Giant cells persist longer than epithelioid cells.

When the capsule is completely formed, the focus shrinks. The nodule is now spherical in shape. This hyalinized connective tissue is called the specific capsule because of its origin from specific granulation tissue (epithelioid and giant cells).

Surrounding this connective tissue zone there is a loose connective tissue layer which Aschoff has designated a nonspecific capsule. This capsule, which arises from the organization of a perifocal inflammation, is thin, and contains lymphocytes as well as a few compressed alveoli. Since this zone of perifocal inflammation is not extensive, the nonspecific capsule is thin. As a result of the shrinking of the focus there is a stretching of the surrounding alveolar septa, resulting in emphysema.

The caseous areas of the primary complex tend to become calcified. Calcium is deposited within the caseation either in irregular masses or in fine strands which run parallel to the capsule, the latter being designated Liesegang's rings. Calcium, which is deposited early, first appears as fine purple stippling and may be very difficult to differentiate from necrotic nuclear remnants.

The process of bone formation, which occurs with great frequency in the

primary foci, extends over a long period of time and is usually observed in older individuals. Two processes occur together: resorption of calcium and the building of bone spicules. From various parts of the specific capsule there is a proliferation inward of a vascular granulation tissue which resorbs the calcium and, at the same time, forms bony bands. A bony shell is laid down along the inner edge of the capsule and extends outward to replace it. Between the bony trabeculae there is fatty and lymphoid bone marrow.

Calcification and ossification are not the only ultimate fates of the primary focus. Huebschmann⁴ believes that the calcium may be completely resorbed without bone deposition. The focus may also be entirely replaced by connective tissue.

Fig. 41.—Progressive primary complex. The primary focus in the basal portion of the left lung is enlarged and caseous. The corresponding peribronchial tracheobronchial lymph nodes are enlarged and caseous.

Progressive Primary Focus.—Fortunately for the human race the vast majority of primary foci go on to anatomical healing. Only a small number of cases react differently. Those cases of progressive primary foci that we have observed occurred early in childhood, usually in the first two years of life. Roentgenologically, a progressive enlargement of the focus was demonstrable. The enlarged focus underwent

central liquefaction and was followed by a bronchogenic dissemination (Fig. 41).

The gross appearance of the cavity in the lungs is that of an irregular shaggy excavation lined by soft cheesy masses. Studded throughout both lungs are large caseous nodules, sublobular and lobular in size. Some of these may also

Fig. 42—Progressive primary complex in the stage of liquefaction. The primary focus in the right lower lobe is greatly enlarged and has undergone liquefaction. The corresponding right inferior and right superior tracheo-bronchial lymph nodes also show softening and liquefaction. The remaining lung tissue in the right lung and the entire left lung is studded with large areas of caseous pneumonia. These caseous foci are part bronchogenic in origin and part hematogenous.

undergo liquefaction and cavity formation. Strikingly characteristic are the regional lymph nodes. They are extensively enlarged and caseous and often show central liquefaction similar to that seen in the focus. The corresponding changes in the focus and its draining lymph nodes identify the primary complex during progression, as well in anatomic healing.

Microscopic examination of the primary cavity reveals a scarcity of encapsulation. The sublobular and lobular areas are characterized by the lack of productive reaction at their peripheries.

The extensive caseation of the tracheobronchial lymph nodes indicates an overwhelming infection in the lymph stream. Autopsy often reveals a large nodular tuberculous dissemination in the parenchymatous organs as well as a tuberculous meningitis. This overwhelming hematogenous dissemination is understandable in view of the extensive pouring of tubercle bacilli from the lymphatic system into the blood stream (Fig. 42).

The Lymph Nodes of the Primary Complex.—Afferent and efferent lymphatic systems are present in the lungs (Blacklock).³ The afferent system extends to the pleura and the efferent system drains into the lymph nodes of the hilus. Pulmonary lymph nodes are present along the course of the bronchi as the lymphatics approach the hilar regions. Those lying in the angle between the trachea and bronchi are the nodes most extensively involved. The superior tracheobronchial nodes are connected with the paratracheal nodes while the inferior tracheobronchial nodes communicate with the mediastinal and, in turn, with the peripancreatic nodes. Thus, the peripancreatic lymph nodes are part of the primary complex. Lymphatic vessels connect the lymph nodes of both hili so that, as the primary complex progresses, caseation may cross over to the nodes in the tracheobronchial region on the opposite side.

Gross Changes.—The tuberculous process is one of rapid and total caseation involving the chain of lymph nodes which extends from the focus to the tracheobronchial angle. On cross section the lymph nodes, which are greatly enlarged, are dry, caseous, and surrounded by a well defined, thin gray capsule. Those within the lung are smaller than those of the tracheobronchial region, since the pulmonary lymph nodes are normally smaller than those outside the lung. The location of the focus is indicated by the region of most extensive in-

involvement of the tracheobronchial lymph nodes. Thus, if the right inferior tracheobronchial nodes are most involved, the primary focus is usually in the right lower lobe.

Anatomic healing of the lymph nodes, characteristic of the primary complex, is similar to that of the focus. All of the lymph nodes in the chain, however, do not progress to calcification. Those within the lung shrink and are replaced by fibrous tissue.

One of the caseous peribronchial or tracheobronchial lymph nodes of the primary complex may soften and rupture into a bronchus, causing an aspiration caseous pneumonia and cavitation. A node may also rupture into a blood vessel and cause an hematogenous dissemination.

Microscopic Picture of the Lymph Nodes.—In the early stage, there is extensive homogenous caseation of the entire node. The formation of specific granulation tissue surrounding the area of caseation, capsule formation, calcium deposition, shrinkage of the node, and ossification occur in the same manner as has been described in the primary focus. Ossification, however, occurs much less frequently in the lymph nodes than it does in the primary focus.

The Stage of Generalization.—*Early generalization* corresponds to the second stage of Ranke. It is tuberculosis developing in the oversensitive body, and may be manifested in various forms. There may be a miliary seeding throughout the lung or the nodules may be sublobular and lobular—large nodular tuberculosis. The large nodular seeding occurs in early childhood, and the majority of these cases coming to autopsy show a tuberculous meningitis with multiple tuberculomata of the brain.

Gross Appearance.—The lungs are voluminous and on section reveal sublobular and lobular yellow areas of caseation which fuse irregularly with the surrounding pneumonic infiltration (perifocal inflammation). Some authors (Jaffe⁵ and Huebschmann⁴) have described a central liquefaction of certain of the foci. Liquefaction of some of these areas will add a bronchogenic factor to an hematogenous spread (Fig. 43).

Microscopic Findings of Early Generalization.—Examination of the yellow areas reveals a caseous pneumonia in which elastic fibers of the involved lung

parenchyma are, for the most part, still intact. There is little evidence of reparative activity in the form of productive reaction at the periphery of these caseous areas. The perifocal reaction, however, is extensive, the alveoli adjacent to the caseous foci containing a serocellular exudate. The sublobular and lobular areas are no different from those seen in chronic pulmonary tuberculosis.

Fig. 43.—Early generalization. Caseous nodules of various sizes are present throughout both lungs. The tracheobronchial lymph nodes are enlarged and caseous. The enlarged nodular dissemination followed soon after the primary complex.

Late generalization is the type of dissemination known as generalized miliary tuberculosis because, in the great majority of cases, the nodules approach the size of millet seed (1 mm.). It occurs in adult life and is present most frequently in cases of extrapulmonary tuberculosis, particularly in skeletal and

genito-urinary tuberculosis (Reisner¹⁰). Pagel¹¹ and Huebschmann⁴ consider that the presence of progressing tuberculosis of a single organ excludes miliary tuberculosis, but Jaffe⁵ disagrees because in 20 per cent of his cases of miliary tuberculosis, chronic pulmonary tuberculosis was also present.

Generalized miliary tuberculosis has a varied pathogenesis. Benda¹² describes a tuberculous periphlebitis which occurs through the extension of a tuberculous organ focus into a vein. The caseous focus—usually a lymph node—ruptures into a vein and, in this manner, leads to a generalized miliary tuberculosis. This type of dissemination, which is rare, presents an even seeding throughout all organs. The tubercles are of the same age and size. Intimal tubercles, as described by Weigert,¹³ are more frequently observed. The areas of caseation which surround the veins extend into the wall of the vessel and form the intimal tubercles or tuberculous endophlebitis, found most frequently in small lung veins. In form and appearance, the Weigert polypoid intimal tubercle is similar to a thrombus. Tubercles in the pulmonary veins will result in a seeding in the organs supplied by the greater circulation. Pagel¹⁴ agrees with Weigert¹³ that the intimal focus is the source of a generalized miliary tuberculosis.

The views of Weigert¹³ are not accepted by Huebschmann,⁴ who observed cases of generalization in which the intimal focus could not be found. Although he has observed tuberculous ulceration of a pulmonary vein and thoracic duct with thick layers of tubercle bacilli, the majority of his cases revealed intimal tubercles of the pulmonary veins and thoracic ducts which were no older than the other miliary tubercles, and were certainly incapable of releasing masses of tubercle bacilli into the blood stream. Rich,¹⁵ Pinner and Kasper¹⁶ also believe that there is not a sudden invasion of bacilli from an intimal focus into the blood stream, but rather that there is a lymphatic drainage from an organ focus, and, in turn, an emptying into the venous circulation. They believe that the tubercle bacilli multiply in the blood stream resulting in an hematogenous dissemination. We, too, feel that the occurrence of hematogen-

ous miliary tuberculosis is due to lymphatic drainage from an organ focus and that the foci most frequently encountered are skeletal and genito-urinary.

Gross Appearance.—Two forms of miliary tuberculosis of the lung must be differentiated: an acute form, in which death occurs within four weeks after dissemination, and a sub-acute or chronic form in which the disease persists for a longer

Fig. 44.—Late generalization. Both lungs are studded with millet seed nodules. The left pleura is thickened and calcified, and on the inner surface soft cheesy particles are still present.

period. In the acute form, the lungs are voluminous and heavy and the lung substance is studded with irregular flat yellow nodules, up to 2 mm. in size, which fuse irregularly with the surrounding pneumonic tissue. In the subacute or chronic form, the lungs are better aerated and contain gray elevated nodules smaller than those found in the acute form and sharply

the nodules are larger and more numerous in the apical ventral aspect than in the posterior basal aspect (Fig. 44).

Microscopic Picture of Generalized Tuberculosis.—In the acute form, the exudative character of the nodules predominates, and the picture is the same as that of sublobular caseous pneumonia, as will be described. The productive reaction in the form of epithelioid cell proliferation is seen only sparsely at the periphery of these areas. These foci are rich in tubercle bacilli. In the sub-acute or chronic form, two types of nodules are seen. One is the typical epithelioid cell tubercle containing one or more Langhans giant cells and surrounded by a dense lymphocyte collection; the other has a central area of caseation surrounded by a wall of epithelioid cells and an occasional giant cell. In the area of caseation the elastic outlines of the former alveoli are often intact, indicating that the process was originally pneumonic in character. The alveoli surrounding the nodules contain little or no exudate.

It is generally believed that cellular epithelioid cell tubercles arise from interstitial tissue. Huebschmann,⁴ however, contends that epithelioid cell tubercles are later stages of exudative miliary foci, on the basis of the fact that in cases where the exudative foci predominate, the duration is no longer than four weeks, whereas when the nodules are chiefly productive in character the duration is more than eight weeks. He believes, moreover, that epithelioid and giant cells occur secondarily and may partly or completely replace the area of caseation, or form a zone around the necrotic area. He regards the presence of elastic fibers of the alveolar septa still intact in the caseous zone as conclusive evidence of tubercles originating as exudative foci. Although Pagel¹¹ concedes that many of the tubercles originate as exudative foci, he maintains that the cellular tubercles are productive from the start.

A miliary dissemination may occasionally be observed in the course of the bronchi and blood vessels. These nodules are free from caseation and are purely productive in character. As the collagen fibrils become thicker and more numerous and the epithelioid and giant cells disappear, concentric nodules of hyalinized connective tissue remain. The perivascular arrangement of the nodules and their loss of specificity as well as the deposition of coal pigment within them make their differentiation from miliary silicosis difficult, a difficulty

stressed by Tesseraux and Olmos.¹⁷ The points of differentiation are that in silicosis the vessel is in the center of the silicotic nodule, no epithelioid and giant cells may be found, and there is a history of exposure to dust.

Isolated Pulmonary Tuberculosis.—The development of tuberculosis in one system of the body has been designated as isolated organ tuberculosis and represents the third stage of Ranke's classification. The involvement of the gastrointestinal tract, as well as the trachea, bronchi and larynx, is considered as part of the system of isolated pulmonary tuberculosis, because tuberculosis in these tissues depends upon, and is the result of, tuberculosis in the lungs. This type develops long after the primary complex has healed. The manner in which it develops has divided pathologists into two groups. One group believes that there is an endogenous exacerbation of the primary focus or an apical or subapical focus. The other group attributes the origin to a new exogenous infection. Unfortunately, the origin of chronic pulmonary tuberculosis can be studied only in its early phase; as soon as extensive cavitation is present such observation is no longer possible.

Endogenous Origin.—Pagel,¹⁸ Schmincke,¹⁹ Huebschmann⁴ and Ghon²⁰ believe that isolated phthisis originates as an endogenous exacerbation of a primary complex or an apical or subapical focus. Such exacerbation has been observed by Pagel¹⁸ in about 25 per cent of his cases, and most frequently in the age group between 16 and 25. The exacerbation is present more frequently in the glandular portion than in the lung focus. Ghon,²⁰ Jaffe⁶ and others also have found exacerbation of the lymph node component of the primary complex with greater frequency than that of the pulmonary focus. In the lymph node the calcified area is encircled by a fresh area of caseation. In the reactivation of the primary focus, an encircling of the older focus by a fresh area of caseation is much less frequent than is the invasion of an outer portion of the focus by a tuberculous granulation tissue. Isolated pulmonary phthisis is the result of a lymphatic drainage from the exacerbated area with subsequent emptying into the venous

circulation. The seeding will occur first in the apical aspects of the upper lobe and the fresh areas produced become an isolated phthisis.

Many investigators doubt the presence of virulent bacilli in the primary complex. Jaffe,²¹ assuming that bone cannot be laid down in the presence of virulent bacilli, points out that the process of ossification is frequently observed in the primary complex. Opie and Aronson²² have found tubercle bacilli in various parts of the lungs and in lymph nodes free from any tuberculous change.

Endogenous Origin from Hematogenous Apical Foci.—

Various types of tuberculous nodules are observed at the apices of the lungs. There are postprimary hematogenous miliary seedings to the apices which, because of lack of progression of the tuberculous process, are abortive tubercles, and have been called by Neumann²³ "miliaris descreta." These areas may change into dense scars—"fibrosa densa"—and the miliary nodules tend to become latent so that there is little likelihood of their reactivation. The scars are seen with greater frequency as puberty is approached. Other postprimary foci seen in the apices of the lungs are small, encapsulated, caseous areas, designated as "Simon²⁴ foci." These foci occur as early postprimary or intraprimary seedings. Histologically they do not differ from a primary focus except that they are surrounded by more connective tissue. Unlike the primary focus they have no regional lymph nodes with corresponding anatomical changes, and have a predilection for the apices. Although calcium is often observed within the caseation, ossification is rarely seen. Many authors believe that isolated pulmonary tuberculosis arises from these foci and from the larger, but otherwise similar, subapical Aschoff-Puhl foci. Whether the Aschoff-Puhl foci are endogenous or exogenous in origin is still debated. Puhl,² who originally described them, believes that they are exogenous, and Aschoff²⁵ concurs. Pagel,¹⁴ on the other hand, contends that they are endogenous and are identical with Simon foci. One reason for Pagel's endogenous stand is that the Aschoff-Puhl foci are found three times as

often in generalization forms of tuberculosis as in isolated phthisis. The only actual differences between the Simon and Aschoff-Puhl foci are that the former are smaller and apical in location. The Aschoff-Puhl focus may show bone deposition, which has been described by Puhl² in three cases. The reactivation of the Simon-Aschoff-Puhl foci may occur in the same manner as the exacerbation in the primary complex. Pagel¹⁴ has shown that these apical foci lie in changed lung tissue. In this region there is scarring and retraction of the lung apices with widening of the apical bronchus. It is through these dilated small bronchi that the invasion from the exacerbated focus extends into the basal aspects of the lung. This bronchial aspiration is believed by many authors, notably Loeschke,²⁶ Schuermann,²⁷ and Huebschmann,⁴ to result in early infiltration, which initiates isolated pulmonary tuberculosis.

Exogenous Origin.—The theory of exogenous origin has been expounded chiefly by the clinician with the aid of the roentgen examination. It was the observation of the shadow and later cavity formation in the infraclavicular region, noted by Wessler and Jaches,²⁸ Assmann²⁹ and others that weakened the theretofore inflexible opinion of pathologists that isolated pulmonary tuberculosis begins in the apices, hence is of endogenous origin. Schuermann²⁷ and Loeschke²⁶ believe that the early infiltrate is the result of a bronchial aspiration from an exacerbated apical focus. That many cases are indisputably of exogenous origin is shown by the presence of early infiltrates in the lung in which no apical foci are present, whereas in other cases, where apical foci exist, no evidence of exacerbation is seen. Assmann²⁹ observed these infiltrates chiefly in the lateral infraclavicular region and concluded that they are found most frequently in individuals who have been in contact with tuberculous patients. He made these observations in a tuberculosis hospital where routine roentgen examinations were done on employees. Although resolution of these foci may occur before the stage of caseation develops, most often they progress to caseation and cavitation. After a cavity is formed, other areas

of caseation and cavitation (daughter cavities) result from aspiration of the liquefied particles containing tubercle bacilli. The early infiltrate in some cases has a more basal location.

Gross Appearances of Isolated Pulmonary Tuberculosis.—

A survey of the lungs reveals old cavities in the apical aspects with caseous lobular pneumonia and fresh cavities and acinous

Fig. 45.—Acinous nodose tuberculosis. There is a "tennis racket" excavation in the right upper lobe with a large branch of the right upper lobe bronchus opening into it. The acinous nodose extension involving both lungs evenly is the result of repeated hemorrhages. There is also calcification of the superior tracheobronchial lymph nodes on the right side.

foci in the basal aspect. The apical portion shows evidence of healing in the form of fibrosis and scarring; the basal portion contains the fresher foci in which exudative reaction predominates. Cavities are present in the dorsal and lateral portions of the apical aspects, and may reach such proportions that they occupy the greater part of the upper lobe. Through

roentgenologic study, often with pathological confirmation, Reisner³⁰ has shown that the oldest cavities are not always present in the upper lobe but may be located in the apical region of the lower lobe. The changes found in both lungs at autopsy may be symmetrical with apical cavities and nodular seedings in the basal aspects; or, one lung may show extensive involvement while the other is relatively free. Hemorrhage markedly affects the disease process, by carrying from the cavities a suspension of tubercle bacilli which is aspirated into other lung parts. The more severe the hemorrhage, the greater the extension into the basal aspect, with predominant large areas of caseation. In the more chronic form acinous nodose involvement dominates the picture (Fig. 45).

The regional lymph nodes are swollen, grayish in color and contain coal pigment in variable amounts. Caseation is seen only in those cases where there is an extensive confluent lobular caseous pneumonia in the lungs, or where there is a generalized lymphatic enlargement throughout the body, with caseation. Caseation of the lymph nodes may occur in the puberty type of tuberculosis described by Aschoff³¹ and later elaborated by Beitzke³²; the nodes are enlarged and caseous but the lungs are similar to those in the adult type. Microscopically, tubercles are invariably found in the glands, with caseation present in their center. Most frequently, however, the tubercles are cellular in character. The lymph sinuses are dilated, a diffuse coal pigment deposition is present and hyalinized connective tissue scars with coal pigment are frequently seen.

The lesions of isolated pulmonary tuberculosis are of two main types: acinous nodose and caseous pneumonic.

Acinous Nodose Tuberculosis.—This is a basic type of isolated pulmonary tuberculosis and is characterized by an extensive productive tissue formation.

The acinus, as the anatomic unit of respiration, was first described by Rindfleisch,³³ and comprises the smallest bronchiole with its alveolar ducts and sacs. Opinions vary concerning its point of origin. Obviously, the more proximally the acinus is assumed to originate in the bronchial tree, the

larger will it be. Thus, Loeschke³⁴ when interpreting the inception of the acinus in the terminal bronchiole reported its size to be 5 mm. But Laguesse³⁵ and Grethmann³⁶ hold that the acinus begins with the division of the alveolar ducts and so state that it is approximately 2 mm. in size.

Gross Appearances.—Fresh acinous lesions are yellow, somewhat scalloped at the periphery, and are not sharply demarcated from the surrounding firm, pneumonic tissue. In the fresh stage, they are difficult to differentiate from sublobular areas of caseous pneumonia, but older lesions are more characteristic. The nodules have a definite garland-like arrangement at their periphery and are gray in color, but in the central portion of the focus they are black. As the foci grow older, they are composed of radiating scars, and the alveoli surrounding the nodules become dilated (perifocal emphysema), resulting sometimes in large blebs. These blebs may be mistaken for cavities on roentgenological examination. As scarring progresses, the typical scalloped appearance is no longer present.

Acinous nodose foci resulting from fusion of acinous foci, or from extension into neighboring alveoli, still retain the typical appearance of the acinous focus, and are found in two forms, the form providing a clue to mode of origin. One form is composed of a large central area containing a good deal of coal pigment; the periphery, which has a scalloped appearance, is composed of pinhead, pearly, elevated nodules. The individual acinous foci are clearly discernible. If the acinous focus is one large nodule, the method of enlargement is extension into neighboring alveoli, either through bronchioles or through direct extension. In the other form, the acinous nodose focus is the result of fusion of smaller acinous foci with individual nodules still discernible.

Acinous nodose tuberculosis may dominate the pathological picture in isolated pulmonary tuberculosis. When it does, the process is slow with an apicobasal progression. Smaller cavities are present in the apical aspects of the upper lobe. The alveoli surrounding the nodule are dilated. This peri-

focal emphysema results in a marked increase in the volume of the lungs. The condition of the pleura also is strikingly characteristic. Except for the apical regions where the pleura is thickened and adherent it is thin, smooth, glistening, and nonadherent (Auerbach and Guggenheim),³⁷ which emphasizes the predominantly productive character of the acinous nodose process. The perifocal inflammation which occurs around the exudative caseous foci and reaches the pleura results in its thickening. In acinous and acinous nodose tuberculosis the exudative caseous process is not extensive and productive reaction soon predominates. The roentgenological appearance of this type of tuberculosis is frequently misinterpreted as silicotuberculosis since the symmetrical nodular seeding throughout both lungs simulates silicosis (Ornstein).³⁸ A questionable history of exposure to dust adds to the difficulty of clinical diagnosis.

Microscopic Picture of Acinous Nodose Tuberculosis.—In the majority of cases, the picture is that of an alveolus filling process. In all foci the process is first exudative in character and later productive. This productive character and a slight tendency to liquefaction and cavity formation are clearly seen microscopically. The fresh acinous foci reveal a group of small caseous and cellular nodules, the caseous areas being surrounded by fibroblasts, epithelioid and giant cells. This productive reaction at the periphery of the caseation is pronounced from the beginning. The alveoli about the foci contain serum, large alveolar cells and lymphocytes. This perifocal inflammation is never extensive. The caseous centers may still reveal, in hematoxylin-eosin stain, the outline of the alveolar septa, the elastic fibers being well retained in the early stages. Swollen fibrin, occasional intact polymorphonuclear cells and nuclear remnants may be observed in the necrotic centers.

As the process continues the productive reaction becomes more extensive and may dominate the lesion. The microscopic appearance is that of small round and oval areas of caseation, surrounded by fibrous capsules which take on coal pigment. Many of the productive nodules are composed of concentrically arranged hyalinized connective tissue, and may be the organized cellular foci seen in the fresh stage, or they may be the result of replacement of a central caseous zone by hyalinized connective tissue. With further healing, there is shrinking and scarring of the foci, with an associated dilatation of the surrounding alveoli (perifocal emphysema). Generally there is an interlinking of old and new foci, the new resulting from recent seedings from cavities or by extension of neighboring foci. The surrounding perifocal inflammation is partially organized so that between the individual nodules there is fibrous tissue within which are compressed alveoli lined by metaplastic cuboidal epithelium.

Kaufmann³⁹ has not accepted acinous nodose tuberculosis as an entity, but, instead, designates this type as tuberculous peribronchitis and contends that the processes are peribronchial and perivascular in nature. Nicol⁴⁰ regards the primary process as productive; Huebschmann,⁴ in contradistinction, claims it is exudative. Pagel¹¹ holds that it may be either. In our experience, the evidence favors primary exudative reaction.

Acinous foci are rarely forerunners of cavity formation although they may be drawn into an adjacent liquefying process. A bronchiole or a small bronchus is occasionally observed in the center of an acinous or acinous nodose focus. This bronchiole or bronchus may undergo caseation and subsequent liquefaction, which, by extending into the surrounding focus, may form a cavity.

Lobular and Lobar Caseous Pneumonia.—This type of tuberculosis is the forerunner of liquefaction and cavity formation. The involvement is generally lobular, rarely lobar, and, when extensive, is designated "galloping consumption." The massive involvement usually follows severe hemorrhage resulting from rupture of an aneurysm within a cavity. The hemorrhage expels soft, cheesy particles, laden with tubercle bacilli with subsequent aspiration into the lower lobes and the ventral portions of the upper lobes. We have seen extensive caseous pneumonia develop after the installation into a cavity of lipiodol for the purpose of visualizing a bronchial communication with that cavity.

Gross Appearance.—In its early stages, the pneumonia is gray or reddish granular in appearance similar to that of any other pneumonia, with yellow areas occasionally present within the consolidation. In its fully developed state, the entire caseous-pneumonic area is yellow and it is flat and indifferently demarcated at the periphery where it fuses with the surrounding firm, flat lung tissue. This perifocal zone is either red or gray and gelatinous in character. Caseous pneumonia may progress to liquefaction and cavity formation, or to encapsulation; if to encapsulation, the greater part of the perifocal inflammation becomes resorbed. Capsule formation and

calcium deposition occur in this process just as in the primary focus.

Microscopic Appearance of Lobular and Lobar Caseous Pneumonia.—In the stage before caseation, the alveoli are filled with fibrin, polymorphonuclear leukocytes, red blood cells, lymphocytes and alveolar phagocytes. The presence of tubercle bacilli differentiates this from other pneumonias. As the process continues, the cellular elements undergo necrosis and the fibrin becomes swollen until the end stage, caseation, is reached. The caseous area is pink and granular and within it outlines of alveoli, bronchioles and blood vessels are often still clearly discernible. A relatively mild productive reaction in the form of fibroblasts, epithelioid cells and giant cells is apparent at the periphery of the caseation. The alveoli surrounding the caseous areas contain a serocellular exudate, the cells of which are alveolar phagocytes, lymphocytes and red blood cells. Polymorphonuclear leukocytes are rarely present. In certain areas cells dominate the exudate; in others, serum. When serum is the chief component of the exudate, the term "gelatinous pneumonia" is appropriate since the exudate presents grossly firm, flat, gray, gelatinous tissue.

Perifocal Inflammation.—This influences the course of the tuberculous process in the lungs. Its extent parallels the amount of caseation. When the areas of caseation become encapsulated the caseous foci shrink and the greater part of the perifocal inflammation may be eliminated through the bronchi. Should the areas of caseation fail to proceed rapidly to encapsulation and shrinkage, the perifocal inflammation is entrapped, the large caseous zones causing compression of the efferent bronchi so that the exudate cannot be eliminated. There is then a fibroblastic invasion and the exudate may become completely organized, resulting in large areas of fibrosis. Those alveoli which are not replaced by fibrous tissue, are compressed, may or may not contain an exudate, and are lined by metaplastic cuboidal epithelium with a glandular appearance. There is characteristically a thickening of the vessel wall, most marked by an increase of fibrous tissue of the intima encroaching upon the lumen.

The Tuberculous Cavity.—This results from the softening and liquefaction of a caseous focus, most often lobular caseous pneumonia. Graeff⁴¹ emphasizes the differentiation between softening and liquefaction. Softening of the caseous

area results from absorption of water whereby the softening focus becomes larger. The process of liquefaction, according to Orth,⁴² Aschoff⁴³ and Schmincke,⁴⁴ is due to the action of proteolytic enzymes formed by the polymorphonuclear leukocytes. The important question is, "Under what circumstances do the polymorphonuclear leukocytes enter the area of caseation?" Graeff holds that the migration of these leukocytes depends upon the hydrogen ion concentration of the caseous material and that there must first be an acidity to produce a chemotactic influence on the leukocytes. Liquefaction may occur in one of two ways: in one form, a demarcation zone of polymorphonuclear leukocytes is present between the area of caseation and the healthy lung tissue (Orth);⁴² in the second form, the leukocytes encircle and invade the area of caseation. The first type of liquefaction was designated by Schmincke⁴⁴ as sequestering, and the latter as an abscess form. A zone of demarcation at the periphery of the caseation develops simultaneously with liquefaction, this zone becoming the inner wall of the cavity as liquefaction is completed.

Cavities may be open or closed. An open cavity communicates with the bronchial tree. It may arise either from liquefaction of a caseous area or from a caseous bronchitis. A closed cavity has no communication with the bronchial tree and arises only from liquefaction of an encapsulated caseous focus. By extension, a closed cavity may become an open one after rupturing into a bronchus or into a neighboring open cavity.

Gross Appearance.—The size of the cavity varies from one which may be seen only microscopically to one occupying almost the entire lung. The average size observed at post-mortem is from 7 to 10 cm. Although cavities rarely pass from one lobe into another, it is possible for such giant cavities to occur as a result of the fusion of smaller cavities. On occasion, they have been mistaken roentgenologically for pneumothorax cavities. The location of the cavity is generally in the upper portion of the upper lobe. The first cavities are observed clinically in the infraclavicular region; as they enlarge, they ex-

tend to the apex and occupy the upper parts of the lobe. Smaller cavities are observed in the lower parts of the lower lobe. The form is variable depending upon the circumstances under which it develops. If it results from a caseous pneumonia and lies in previously unchanged lung tissue, its form will be fairly regular, being club-shaped, oval or round. If it develops in an area surrounded by cirrhotic tissue, or if multiple cavities fuse with one another, or if a fresh liquefaction ruptures into an older cavity, irregularly formed cavities result.

After expulsion of the liquefied cheesy material the boundary of the cavity is formed by a capsule. Its inner wall is lined by a thin, dirty gray membrane which may be easily scraped away. Attached to this inner layer, or pyogenic membrane, are soft cheesy particles known as Koch lentils, which are laden with tubercle bacilli. These cheesy particles are numerous in the early stages of cavity formation, but as the cavity progresses they diminish. Beyond the pyogenic membrane is a layer of red tissue forming a narrow zone of vascular granulation tissue. The third layer—beyond the vascular granulation tissue—is firm, flat, gray, and may fuse with the pleura where the cavity is situated superficially. The width of the third layer increases with the age of the cavity. In long-standing cavities there are numerous trabeculae which represent thrombotic pulmonary arteries. Their thickness depends upon the size of the involved vessel. On cross section they have a gray or red appearance and the lumen of the vessel is obliterated.

When the elastic lamellae of the vessels are preserved, slowing of the blood stream, secondary to compression of the vessels, results in thrombosis. Sometimes the caseation quickly extends to the arteries resulting in a destruction of their elastic lamellae with the subsequent formation of aneurysmal dilatation of the vessel (aneurysm of Rasmussen). These aneurysms are situated within the cavity in the region of the inner wall and their rupture usually results in a fatal hemorrhage; the bronchi, cavities and alveoli fill with blood so that death results from suffocation.

Microscopic Appearance of the Cavity Wall.—Microscopically, the wall of a cavity varies with its stage of development. The term "finished cavity" is applied when the liquefied material has been expelled and the zone of demarcation is complete. The wall of the great majority of finished cavities is composed of three layers. The innermost zone, designated pyogenic membrane, is made up of a base of thick bands of fibrin containing chiefly intact polymorphonuclear leukocytes as well as fibroblasts and lymphocytes. Beyond this is a zone composed of dilated capillaries which accounts for the red appearance observed macroscopically in the second layer of the cavity wall, *i. e.*, the layer of vascular granulation tissue. Surrounding this is a layer composed of thick fibrous tissue that is poor in blood vessels. The width of this zone depends upon the age of the cavity—the older the cavity, the wider the zone. This third layer arises from the organization of perifocal inflammation around the original caseous pneumonia; as this organization progresses, the width of the layer increases. Although compressed alveoli are seen in the first two layers of the cavity, they are present in greatest number in the third, or fibrous layer.

Cavity Healing.—This may occur with or without the closure of the lumen. Huebschmann,⁴ Graeff,⁴⁴ Tchertkoff and Bobrowitz,⁴⁵ and others have described the spontaneous closure of cavities. Huebschmann believes that only cavities the size of a walnut or smaller are capable of spontaneous closure. Closure is the result of the shrinking of the fibrous wall (the vascular granulation tissue having been converted into fibrous tissue) and the filling in of the lumen by granulation tissue. Microscopically the end stage of closure is a ringlike arrangement of fibrous tissue encircling a small slit. At the periphery the fibrous tissue radiates irregularly into the surrounding lung.

The other form of cavity healing may occur in a vomica of any size. The pyogenic membrane is replaced by bands of fibrous tissue, the wall then being composed of hyalinized connective tissue laden with coal pigment. We have observed epithelialization of cavities in two cases. The epithelium lining the cavity was squamous in type and extended onto the trabeculae. Beyond the epithelium was a wide layer of vascular granulation tissue. Here and there, in the cavity wall, an epithelioid-giant cell tubercle was observed.

Cavity healing has been greatly aided by artificial pneumothorax and thoracoplasty. Collapse therapy approximates the

walls of the cavity as well as of the bronchi. The amount of scarring surrounding the cavity is much greater in surgically compressed lungs than in those of nonsurgical cases. The reason for this is the organization of perifocal inflammation which cannot escape through the bronchi because of their compression. This increase in the encircling scar tissue undoubtedly aids in the contraction of the vomica. Backmeister⁴⁶ and Coryllos⁴⁷ believe that the closure of cavities is preceded

Fig. 46.—Status postthoracoplasty. Note a slitlike excavation in the right upper lobe. Two bronchi leading to this excavation were closed. The right upper lobe is compressed and the pleura overlying it is extensively thickened. There are two Aschoff-Puhl foci in the left lung.

by closure of the bronchi. We have studied at autopsy a few cases in which negative sputum had resulted after artificial pneumothorax; there was an approximation of the walls of a large bronchus opening into the cavity, although the cavity was patent and a probe could be passed from the bronchus into the excavation. It is highly probable that the negative sputum was the result of a functional closure of the bronchus, for, although a probe could be passed through the potential

lumen by pushing aside the approximal walls, sputum could not have so passed.

With continued bronchial compression, granulation tissue of a cavity wall may extend across the obliterated lumen of the bronchus so that the bronchus ends blindly at the cavity wall. Another result of compression of the bronchus by artificial pneumothorax is the proliferation of granulation tissue within the bronchial lumen itself, obliterating the bronchus at its junction with the cavity resulting in a cul-de-sac (Fig. 46).

Spontaneous Pneumothorax (Tuberculosis).—Spontaneous pneumothorax and its sequelae must be considered as complications of cavity formation inasmuch as their occurrence is generally the result of perforation of a cavity into the pleural space. These perforations occur when an area of caseous pneumonia extends to the pleura, resulting in a caseous pleuritis. As liquefaction sets in, not only is the pneumonic area involved but also the caseous pleuritis.

Cases complicated by perforation are not so numerous as cases of uncomplicated isolated pulmonary tuberculosis. The reason is that the perifocal inflammation surrounding the caseous pneumonia usually extends to the pleura where it sets up a nonspecific fibrinous pleuritis leading to fibrous tissue formation and an obliteration of the pleural space. The fate of spontaneous pneumothoraces is variable; as a rule, after continuous deflation, the perforation is sealed off by a proliferation of granulation tissue extending inward from all sides of the pleural opening, but this sealing off occurs only in barely perceptible perforations. The result of the spontaneous pneumothorax is a tuberculous effusion into the enlarged pleural space, followed sooner or later by mixed infection. The organisms most frequently found with tubercle bacilli are the streptococci, staphylococci and pneumococci.

Chronic Hematogenous Tuberculosis.—Pagel¹⁴ has elaborated upon this form of tuberculous involvement, which must be differentiated from isolated pulmonary tuberculosis. The involvement of the lungs is characterized by a symmetri-

cal nodular seeding, most marked in the apices and decreasing toward the bases. The nodules may appear as acinous foci, and as scarring occurs, the surrounding lung tissue becomes emphysematous. The result is a chronic hematogenous emphysematous tuberculosis. Simon and Aschoff-Puhl foci are seen frequently in this type of dissemination. Typical thin-walled excavations (punched-out cavities) lying in unchanged lung tissue are found in the dorsal and subpleural aspects of the upper lobes. Microscopically these cavity walls reveal a thin zone of vascular granulation tissue, and, beyond this, a narrow layer of connective tissue.

The origin of this type of tuberculosis, according to Pagel,¹⁴ is either from apical foci (Simon, Aschoff-Puhl) or from peripheral organs such as the skeletal system and the genito-urinary tract. The primary complex usually shows no sign of exacerbation. Involvement of the larynx and gastro-intestinal tract occurs in 20 to 35 per cent of cases, whereas in isolated pulmonary tuberculosis these organs are involved in approximately 70 per cent of cases. This is explained by the fact that in isolated phthisis there are large excavations from which tubercle bacilli are expelled. Through expectoration and swallowing these bacilli infect the larynx and the gastro-intestinal tract. In chronic hematogenous dissemination, however, since only small excavations are present and since the process is predominantly productive in character, fewer bacilli are liberated into the larynx and gastro-intestinal tract.

CLINIC OF DR. BELA SCHICK

SEA VIEW HOSPITAL

TUBERCULOSIS IN CHILDHOOD

WHEN the tubercle bacillus invades the human organism for the first time, the clinical and pathological pictures of the disease following this invasion show distinct and significant features which are quite different from those seen in a case where the tubercle bacillus attacks an individual previously infected with tuberculosis, whether this attack is brought about by a superinfection from without or within. Since, in the majority of cases, the first invasion of the bacillus occurs during the period of childhood, the generally accepted terminology for the form of tuberculosis observed during childhood is "the childhood type of tuberculosis." By this nomenclature is meant that if an adult is successfully invaded by the tubercular bacillus for the first time he also develops the "childhood type of tuberculosis."

The tubercular infection usually takes place by inhalation of the germs into the lungs. Other ways of infection, as cutaneous, congenital, intestinal, etc., seldom occur. Intestinal infection is usually caused by the ingestion of raw milk containing the bovine type of the bacillus. In the United States where the milk production is rigidly supervised and where the milk is either pasteurized or not used until boiled, the occurrence of intestinal infection is negligible. That such an infection can be easily produced was proved by the tragic accident in Luebeck, Germany, where by mistake, virulent bacilli were fed to newborn children in the attempt to vaccinate these children with the attenuated *Bacillus Calmette-Guérin*.

The gastro-intestinal wall is capable of being permeated by the tubercle bacillus particularly during the first month of life.

The primary effect in tuberculosis is established at the place of entrance of the tubercle bacillus in an alveolus or in a small bronchiolus. It was difficult to find early stages of the disease. A real exudative inflammatory process is established in the form of a pneumonia caused by the tubercle bacilli. The bacilli travel immediately after the infection along the lymphatic vessels to the regional glands. Bronchopulmonary and bronchial glands become infected on the same side where the primary focus is situated. On the lymphatic way the tubercle bacilli proceed further to the regional glands in the bifurcation. Clinically and pathologically the primary focus and its regional glands compose the first stage of the disease—the so-called “primary complex of tuberculosis” (Ranke). Two to three weeks are required to develop symptoms of the first stage that can be microscopically detected, for their clinical manifestation four to six weeks and more may be needed, from the localization of the diseased gland we can infer the situation of the primary forms.

In the majority of cases the primary focus is very small, frequently located subpleurally and is sometimes difficult to detect even microscopically. Usually it is not larger than a pea or bean. According to Ghon's statistics, 174 out of 184 cases had a primary focus smaller than a hazel-nut. Eighty-three were as large as a pea and 27 were as large as a bean. Needless to say one is unable to detect such a small infiltration by percussion or auscultation and even the x-ray does not always reveal such a small focus as long as it is not calcified. Only in those cases where the primary affection grows by spreading into the surrounding tissues and so forms large exudative infiltrations or later caseous masses or cavities that the diagnosis becomes possible mainly by means of x-ray examination.

Usually only *one* primary focus is found. Ghon and Winternitz found among 606 cases only 28 (4.62 per cent) with two primary foci. More than two primary foci are still

rarer. Ghon and Kudlich found 18 calcified primary foci in a three-and-one-half-year-old girl. The establishment of the primary focus inhibits the development of new primary foci. Multiple primary foci are apparently only developed during the incubation time of the tuberculous infection. The distribution of the primary focus was, according to Ghon, as follows:

	Per cent.	Per cent.	
R. U. L.....	196	29	The right side is more frequently involved (54 per cent), the right upper more often than the right lower lobe.
L. U. L.....	167	25	
R. L. L.....	126	19	
L. L. L.....	125	19	
R. M. L.....	57	8	

In his classical treatise Ghon failed to find the primary focus only in 0.5 per cent of the 790 cases. In 729 cases (92 per cent), the primary focus was found in the lungs. Only 20 cases (2.5 per cent) showed an extrapulmonary focus, 14 of them in the intestinal tract. Only one case was found where the primary focus was in the right tonsil. The teachings that the tonsils are frequently the portal of entrance of tuberculosis is erroneous.

There are already, during early stages of the infection, animal experiments which prove that the tubercle bacillus proceeds further than the regional lymph nodes. The lymphatic way leads to the ductus thoracicus and further on to the blood circulation. In this way, tubercle bacilli may reach different organs of the body. In most of the cases this advance does not produce any clinical or anatomical signs. Thus the majority of cases develop only to the syndrome of the primary complex. In cases of mild infection or when the organism has a good resistance, the primary focus heals by scar formation, frequently with some calcification. The healing process in the infectious gland is somewhat slower, the inflammatory process leading to caseation and later after many months to shrinkage and calcification. It is an interesting fact that if the primary focus be small, it may heal entirely like the primary lesion of syphilis. In the center of the regional gland one still finds,

even in cases of so-called "complete cure," living tubercle bacilli, the existence and life of which can be proved by their ability to infect guinea-pigs. The clinical arrest of the disease requires at least two or three years. The primary focus, which is, as mentioned before, frequently invisible roentgenologically becomes conspicuous on the plate when calcification takes place. It can be easily diagnosed in this stage of incomplete or complete healing by the presence of a definite bone- and projectile-like round shadow at a distance from the hilus. Shadows of enlarged lymph nodes particularly in the hilus and paratracheal region belonging to the primary complex are visible eventually without calcification and become more distinct in the event of calcification.

These radioscopic findings are important, as calcification in other than tubercular processes is very rare. The diagnosis of a previously established tuberculous infection can thus be made.

The further advances of the disease lead to the so-called "secondary stage" which is characterized by the spreading and generalization of the tuberculosis virus. There are four ways of dissemination:

(1) Lymphatic, (2) hematogenous, (3) bronchogenous, (4) enterogenous. I mentioned the fact that even in cases where clinically and anatomically only the primary complex becomes visible one has to assume that tubercle bacilli travel along the lymphatic way into the venous part of the circulation. Thus the lymphatic way becomes a hematogenous way. The hematogenous way may be taken by arrosion of the pulmonic vein by an adjoining tuberculous lymph gland or by arrosion of the innominate vein at the angle near to the vena cava superior. In the first case, tubercle bacilli reach directly the veins leading to the left heart without having to traverse the entire pulmonic circulation. In the latter case of arrosion of the innominate vein tubercle bacilli arrive first at the right ventricle and can be filtered out into the lung capillaries and reach only the left heart and the large circulation after this filtration. Miliary tuberculosis of the lungs is thus more easily

established and the organs of the larger circulation get smaller amount of tubercle bacilli. In case a pulmonic vein is arroded the entire mass of tubercle bacilli appear in the left ventricle and are thrown into the large circulation. These bacilli may settle down in any organ. The generalization of the tuberculous infection is therefore possible. It is easily understood that the fate of the individual is determined by three factors. First, by the intensity of the invasion; secondly, by the resistance of the individual; thirdly, by the importance of the organ attacked by the bacilli. Invasion by a few tubercle bacilli will certainly occur very frequently but the organism is able to destroy them within the circulation or arrest any localized small damage before they produce clinical symptoms. It may happen that some bacilli which became settled in an organ (brain, kidney, bone, etc.) are only temporarily made innocuous, as long as the resistance of this organ is satisfactory. In case of injury or lowered resistance such dormant foci may gain better foothold and develop symptoms. It is also possible that with lowered general resistance circulating tubercle bacilli are able to obtain more easily localization in an organ. In case of injury circulating bacilli settle down in the region of the tissue damaged by this injury. It seems to be that even many months after the primary focus is established insignificant foci early disseminated, become manifest and dominate the clinical picture. But it has to be remembered that the primary complex still exists if tuberculous foci (brain, bone, joint, etc.) are scattered far away from it. These foci are secondary (metastatic) foci derived from the primary complex.

If the invasion is a very massive one, miliary tuberculosis of all organs may follow (galloping tuberculosis) with fatal outcome. In case of less massive invasion, it makes a difference in the prognosis what organ is the seat of the tuberculous process. A tuberculous process in a metacarpus bone is less dangerous than a process in the brain or in a vertebra. The breakdown of the tuberculous focus in the metacarpus bone leads to suppuration. In this way the entire tuberculosis focus can be excreted through a fistula. But the tubercle in the

brain leads easily to the development of a tuberculous meningitis, a disease with 100 per cent mortality. At the autopsy of a case of tuberculous meningitis, as a rule, tuberculous foci are found in the brain and along the vessels. Tubercle bacilli liberated from these foci infect the meninges. The tuberculous process in a vertebra is located in the body of the vertebra. This is a dangerous localization, the suppurative process may destroy the continuity of the spinal column or it may extend either toward the medulla compressing it and threatening again the development of a tuberculosis of the central nervous system or it may proceed toward the anterior surface producing a sinking abscess. Long lasting suppuration may produce amyloidosis.

Fortunately the vast majority of cases with tuberculous infection escape the visible settlement of tubercle bacilli and production of metastatic foci in spite of the fact that tubercle bacilli invade the circulation. Löwenstein was able to show that in special culture taken from the blood of individuals with tuberculosis tubercle bacilli grew. These findings have been questioned. Many authors were unable to confirm his statement. A study of cases in Sea View Hospital (Lydia Shapiro) showed only 4 to 5 per cent positive results among progressed cases of tuberculosis. Löwenstein published much higher figures. However, he has more experience in this matter; in his latest publication he points out that he has made 24,000 blood cultures. It must be admitted that a better acquaintance with the method may facilitate a higher percentage of positive results. From clinical viewpoint it seems plausible to accept the results of Löwenstein, because many clinical facts can only be explained on the supposition that tubercle bacilli invade from time to time the circulation. This invasion is most likely not a continuous one but rather an interrupted one: it can be said that there is no continuous dripping or raining of the bacilli into the circulation but the invasion may be compared to a hailstorm of tubercle bacilli lasting for a few hours and a more or less frequent recurrence thereof.

The third way in which the tubercle bacillus can spread is

within the branches of the bronchial tree. Already, in the primary stage the focus of the tuberculous infection readily extends to the neighboring ramifications of the bronchial tree, this increasing the size of the primary infection. The primary affection is in direct connection with the air passage; it is an early form of open tuberculosis. Tubercle bacilli and tuberculous material accumulate in the air passages near the primary affection by coughing and by the normal movement of the bronchial secretion tubercle bacilli reach the more centrally located bronchial ramification. With the following inspirations, such infectious material is readily aspirated to other parts of the same lobe of the lung or in other lobes of the same side. If the tuberculous material is coughed up higher, that is up to the level of the bifurcation, aspiration of this material into the main bronchus of the *other* lung is possible. The dosage must again be considered when determining how much damage will follow such a bronchogenous spread. A small amount may be destroyed without provoking visible alterations. Larger doses will create an inflammatory exudative process at the site of their settlement. The size of this secondary focus is usually much larger than the primary affection. Therefore percussion and auscultation will give more definite signs (dulness, bronchial breath sounds and râles) and the x-ray film will show more or less intensive shadowing. This fact should be remembered in judging its pathology. The large size of the process indicates rather that one is not dealing with a primary focus but with secondary foci established by bronchogenous spread. Massive doses of tuberculous material brought up from destructive tuberculous foci may lead to an intensive disseminated tubercular process. At autopsy, the process is characterized by the so-called "acinous" type of tuberculosis (Aschoff). In some cases the bronchogenous spread is initiated by the breakdown of a tubercular gland next to a bronchus. The tubercular process finally arrodes the bronchus and the content of the liquefied and caseated lymph gland is emptied into the bronchus. From here the material can be aspirated in the same way as described above.

The fact that the primary invasion of the tuberculosis takes place almost always in the lung is therefore a decided disadvantage. This localization entails the danger of bronchogenous spread with all its potentialities. A primary focus in the subcutaneous tissue has the other ways of spread (lymphogenous and hematogenous) open but not the bronchogenous. The latter can only be reached indirectly after a pulmonary focus is established on lymphogenous or hematogenous way. The extrapulmonary primary complex has therefore a somewhat better prognosis. Only the danger of lymphohematogenous spread to miliary tuberculosis or tuberculous meningitis looms over the patient.

The diagnosis of childhood tuberculosis at the time of the primary complex is very difficult and frequently impossible if we rely only upon clinical symptoms. As mentioned before percussion and auscultation reveal nothing as long as the primary focus remains small and this is the case in the great majority of cases. The enlarged lymph nodes are so situated that they escape our usual clinical examination. The value of percussion and auscultation for diagnosis is rather questionable. The "Smith phenomenon" and the "Espine sign" may be of value if the physician trains himself specially for elucidating them. Even then errors are too frequent. The x-ray examination does not reveal the primary focus in its fresh state so long as it is small. A calcified primary focus means healing and that it is not a recent affair. Only primary foci enlarged by bronchogenous spread may be seen on the film. The x-ray examination gives a better result in revealing shadows in the hilus region representing the cluster of enlarged lymph nodes. Enlarged lymph nodes can be seen on the x-ray film if they are situated along the trachea, where they produce a shadow in the form of a date reaching out into the lung field. The bifurcation glands which are regularly involved and sometimes very large are so situated that they cannot be visualized on the film. They lie behind the heart shadow. The oblique exposure does not always improve the visualization. Other clinical signs must call our attention to the possibility of the

diagnosis of tuberculosis in the stage of the primary complex. The general toxic effect of the tuberculous infection is shown in *three important* symptoms: (1) loss of appetite, (2) loss of weight, (3) fever of rather mild or medium intensity. Cough, night sweats may be present but are not conspicuous. During infancy, especially in younger infants, the diagnosis of tuberculosis can be made on account of the presence of enlarged lymph nodes on the trachea or main bronchus of either side. The small lumen of the trachea or of the main bronchus becomes very narrow so that especially the expiration becomes labored. An expiratory grunt resembling asthma is produced. In such cases a peculiarly high-pitched cough, sometimes spasmodic, resembling whooping cough, may develop. These symptoms are very characteristic for enlarged tubercular lymph nodes at the bifurcation. The compression of one main bronchus may lead to an atelectasis of the upper lobe.

The second way of diagnosing the presence of tuberculosis in the primary stage is by examining the stomach content obtained by lavage or by examining the feces for tubercle bacilli. Even though an infant or young child coughs he does not expectorate the sputum but swallows it. Rarely are we able to get sputum for examination before the sixth or seven year of life. The sputum swallowed during the night can be recovered by lavage in the morning before breakfast. Tubercle bacilli are frequently found in this manner. Also the feces may be examined. The third method of diagnosing tuberculosis in the primary stage is by testing with tuberculin, which I shall discuss later.

The second stage of tuberculosis, the stage of generalization (Ranke), is somewhat easier to diagnose. The tuberculous foci appearing in the bones or joints are, for most cases, so conspicuous that they will not be overlooked. Predilections of localization are the phalangeal and metacarpal bones, furthermore, the epiphyseal region of the long bones and the body of the vertebral bones. The epiphyseal affection of the long bones precedes the joint involvement. Knee, elbow, wrist, ankle and hip joints are most frequently the seat of tubercu-

losis. The monarticular involvement and chronicity differentiate them from rheumatism. Pleurisy and peritonitis are also easily detected. Secondary foci within the lung, mostly originating through bronchogenous spread, appear frequently large enough to yield to diagnosis by percussion or auscultation. x-Ray examination of the chest is essential, including pictures taken in an oblique position. Shadows due to infiltration situated behind the heart may be otherwise overlooked. The symptoms of meningitis tuberculosa are, in the beginning, difficult to evaluate. A change in the behavior of the child, headache, vomiting and slowing down of the pulse rate should be watched with the idea in mind of an impending tuberculous meningitis. A symptom of active tuberculosis, very helpful for diagnosis, is the appearance of tuberculous skin lesions. Lichen scrofulosus and tuberculosis cutis verrucosa are very characteristic pictures. Of especial importance are the papulonecrotic tuberculides, which are pathognomonic for active tuberculosis and relatively frequent in children of one to two years of age. In cases of miliary tuberculosis such papulonecrotic tuberculides may be very numerous, resembling somewhat in distribution and appearance chickenpox. Papulonecrotic tuberculides are a very definite proof of an active tuberculous process combined with an invasion of tubercle bacilli into the circulation. An intensive eruption of tuberculides is always an alarming symptom as it demonstrates an intensive invasion. In all cases of secondary localization one must realize that the primary complex within the respiratory tract is still present in active form. It may be that the primary affection has become arrested, but the regional lymph glands are certainly actively involved. It is self-understood that the bone, peritoneum or meninges cannot be the seat of the primary affection; they can only be reached by the way of a lymphogenous or hematogenous spread. Pleurisy may develop in direct continuation of the primary affection as the latter is so frequently situated subpleurally near to the surface. But pleurisy develops in the majority of cases as a secondary manifestation and as a part of generalization.

The peculiar picture of *scrofulosis* is characterized by conjunctivitis, keratitis phlyctenulosa, blepharitis and swelling of the region of the lips, etc.; usually the lymph glands in the submaxillar region are swollen and caseated. The picture is lately less frequently seen in our country. Its significance for the diagnosis of tuberculosis is extremely great. Sometimes only conjunctivitis phlyctenulosa is present and just as valuable for the diagnosis of childhood tuberculosis as a positive tuberculin test. Why certain children with tuberculosis develop the syndrome of *scrofulosis* is not known; an additional factor is necessary to change the regular secondary form of tuberculosis into *scrofulosis*. Certain authors feel that the manifestations of *scrofulosis* are only the peculiar reaction of tubercular children to other infectious agents (staphylococci, streptococci, etc.), other authors remarking about the declining incidence of *scrofulosis* think that the increased intake of vitamins is responsible for the reduction.

Another syndrome is usually a sign of an active tubercular process, that is the *erythema nodosum*. In over 90 per cent of the cases of *erythema nodosum* the presence of active tuberculosis can be ascertained. The appearance of these prominent somewhat tender nodes of different size in the skin over the tibia is so conspicuous that the diagnostic value for tuberculosis cannot be overstated. The eruption is rather an early manifestation of generalization of tuberculosis.

The *x-ray examination* is an almost indispensable help in the diagnosis of tuberculosis of the lung. However, it must be stated that the diagnosis should not be based exclusively on the *x-ray* picture. All other clinical and laboratory measures must be considered. Especially an increased hilus shadow may lead frequently to a wrong interpretation, because the intensity and form of hilus shadows is very difficult to judge. It varies normally in different individuals. One should never forget that the *x-ray* picture shows only shadows and not the nature of the underlying process. Infiltrations in the lung fields may for instance be pneumonic in nature even in a tubercular child.

Next to the x-ray examination testing with tuberculin is one of the most important aids for establishing the diagnosis of tuberculosis. It is today a common knowledge that the cutaneous (Pirquet) or intracutaneous (Mantoux test) application of tuberculin produces at the site of application an inflammatory reaction, if the individual has been previously infected with tubercle bacilli. Individuals entirely free from tuberculosis do not react even to large doses of tuberculin. The positive test is a sign of allergy existing in a tubercular individual. Pirquet, the discoverer of the test bearing his name, used concentrated old tuberculin for the cutaneous test. He constructed a borer for it. In case intracutaneous testing is preferred, high dilution of tuberculin must be administered. In active tuberculosis the sensitiveness to tuberculin is usually very high; 0.1 cc. of 1:10,000 gives already a relatively intensive reaction. In less active cases and arrested cases the sensitiveness to tuberculin may be lessened and 0.1 cc. of 1:2000 is necessary to get a positive reaction. Two to three years after complete arrest of the disease the sensitiveness may be much lower and 0.1 cc. of 1:100 = 1 mg. old tuberculin has to be injected. Occasionally one must use still higher doses. A lower sensitiveness also exists during the first weeks of the disease. The safest way to discover tuberculosis in a child is to perform a Pirquet test (cutaneous test) with concentrated old tuberculin. Only in case the Pirquet test is negative an intracutaneous injection of 0.1 cc. of 1:100 (Mantoux test) may be done. This Mantoux test must be made twenty-two or forty-eight hours after a negative Pirquet test. If more time has elapsed, the Pirquet test must be repeated, before a Mantoux test with 0.1 cc. of 1:100 is performed. The Pirquet test increases eventually the sensitiveness to tuberculin. Other authors prefer not to make the Pirquet test but start immediately with the intracutaneous test (Mantoux) with a dilution of 0.1 cc. of 1:10,000 or 0.1 cc. of 1:2000. If this test is negative the dose of tuberculin must be increased. In my experience the testing with 0.1 cc. of 1:2000 is too large a dose for a case of active tuberculosis in a child. A resulting tempera-

ture rise is frequently seen and this should be avoided. Active cases show regularly positive reaction with 0.1 cc. of 1:30,000; some cases are so sensitive that they react to 0.1 cc. of 1:100,000 and even 0.1 cc. of higher dilution.

The positive Pirquet or Mantoux test proves the existence of a tubercular focus in the body, but not necessarily an active process. In infants and children up to three to four years the positive test can be taken as a sign of a relatively active process, because the tuberculous affection needs at least two to four years until it is arrested. The older the child the less we can rely on the positive test as a sign of an active tuberculosis. Beyond seven or eight years many children of the lower economic strata (25-40 per cent of the children) depending upon difference in exposure show a positive test. In this age period the negative test has more weight for the diagnosis. In case of doubt whether a process is tubercular in nature or not, the *negative* test (intracutaneous 1 mg.) will decide *against* tuberculosis. *It is therefore incorrect to state that the tuberculin test in children over seven to eight years has no value.* In this age period the positive test has to be taken cautiously and be weighed together with all other clinical symptoms, before any decision is made, *whereas the negative test is more decisive than the positive test.*

Lately purified tuberculin is used for diagnostic purposes. The practitioner will do better to use at present old tuberculin, until more experience accumulates in its use.

Rubbing of concentrated tuberculin into the skin (Moro test) and the "patch test" gives also satisfactory results similar to the Pirquet test.

Pirquet taught us that the tuberculous infection leads to allergy against the tubercle bacillus and tuberculin. Allergy means altered reactivity. The organism reacts to the reintroduction of the tubercle bacillus quicker and better than at the time of the first invasion. The positive tuberculin test is an expression of the allergic state. Pirquet and after him many authors saw in the established allergy a basis of improved resistance against superinfection from without or within. The

higher resistance of a tuberculous individual was already demonstrated before Pirquet. The fundamental experiment of Koch showed that a tuberculous guinea-pig superinfected subcutaneously with tubercle bacilli heals this new infection quickly. Lately the statement that a child previously infected with tuberculosis has a better resistance against superinfection was questioned by Rich, Myers and Stuart. These authors pointed out that the intensive sensitiveness against tuberculosis is rather a disadvantage than an advantage for the child reexposed to a superinfection. Although it has to be admitted that a hyperergic state may have occasionally a deleterious effect in case of superinfection, the great majority of cases do not show such a high grade of hyperergic reactivity. Therefore the original idea that the primary complex has a beneficial effect on later in life occurring superinfection must be maintained.

The story of the tuberculous infection is not finished with the first chapter of the primary complex and the second chapter of generalization. I mentioned before that within the first years after infection the appearance of new foci may be anticipated. There is only a certain balance between the virulence of the tubercle bacillus and the allergic defense mechanism of the body. The danger of massive invasion and massive generalization diminishes quickly after the first six or nine months of the tubercular disease have elapsed. The ultimate outcome of the infection can then be judged more easily. We shall know how much exudation or destruction is going on, especially in the lung. If these first six to nine months go by without an intensive lung involvement and without too much generalization or without establishing a meningitis tuberculosa, the defense mechanism will work more effectively and arrest the disease in the vast majority of cases. Of course the patient has to be carefully followed up. It may happen that after a relatively quiescent period in the disease new foci appear within the lung parenchyma. The localization of such foci is frequently in the subclavicular region, sometimes even

in the apical region. We assume that this localization may have been present during the earlier periods of the disease without a development of definite symptoms. Loss of appetite, a moderate cough, slight elevation of temperature, will be the warning signal that some flare up has occurred. Percussion reveals some dulness in the infraclavicular region. Râles may be heard. α -Ray examination reveals some shadowing in this region. This infraclavicular infiltration can resolve again and the arrest of the disease will be established.

In other cases the infraclavicular or apical lesion will progress and will lead to the "adult type" of tuberculosis described elsewhere in this volume. There are two very interesting facts about this development: (1) it is particularly the prepuberty and puberty period of life which have a decided influence upon the breakdown of the resistance toward the tubercle bacillus, and (2) as these two periods appear in girls earlier than in boys the development of the "adult type" of tuberculosis is seen earlier in girls than in boys; in girls usually between nine and thirteen years of age, in boys two to three years later. The pediatrician has more opportunity to see girls suffering from the "adult type" of tuberculosis. It is our impression that the flare-up of the tubercular process develops from superinfection from within more frequently than from superinfection from without. This question must be settled for the individual. Superinfection from without is certainly very important and should be prevented. The resistance of the individual is only a relative one. Intensive superinfection from without can be just as dangerous as a superinfection from within. Personally I think it is better not to insist on a definite decision as to which form of superinfection is more frequent. Both must be fought off. Keeping up the resistance of the individual is necessary under all circumstances and the removal of an individual with an open tuberculosis in the environment of a child is always imperative. There is no doubt that the repeated exposure to superinfection should be avoided at all times. The intensity of the infection is increased by repeated superinfec-

tion. I believe that the early removal of a case of open tuberculosis from the newly infected child and especially infant, will diminish the amount of infectious material in the preprimary, primary and postprimary stage. I have demonstrated (with Karelitz) that in an acute infectious disease like measles the immediate removal of the diseased child from his siblings facilitates the protection of the latter against measles. Much more convalescent serum is necessary, if one wants to protect such children against measles who are continuously exposed to measles during the incubation time.

PROGNOSIS, PROPHYLAXIS, AND THERAPY

The prognosis of the childhood type of tuberculosis depends upon the age of the child, the intensity of the infection and extension of the disease. The younger the child the greater the danger for massive invasion and therefore for miliary tuberculosis and tubercular meningitis. As mentioned before, the first six to twelve months after the onset of the infection are especially dangerous. The more time which elapses the less frequently does an intensive generalization occur. Destructive processes in the lungs have a bad prognosis in the majority of cases. Destruction leading to cavitation and further to intensive bronchogenous spread progresses very quickly. The cavities are acute cavities; I believe that most of such cases are due to a very massive infection. Disregarding the mentioned danger of massive and repeated exposure the prognosis of a tubercular infection in childhood is far better than was thought before the advent of x-ray examination and tuberculin testing. Whereas before frequently only the violent forms of disease were discovered, we are now able to make the diagnosis much earlier and in individuals who never would have been known to be infected. The incidence of tuberculosis in childhood can be diminished and is greatly diminishing through the intensive battle against tuberculosis in the adult. The discovery of tuberculosis among the parents and other members of the household (servants, maids, visitors, relatives)

and also among teachers must be followed by the removal of the case of open tuberculosis from the environment of the child. The exposure to tuberculosis will be thus delayed until the school age and later, when the infection may be less intensive and the exposure less frequent than within the family. I expect that in this way the incidence of tuberculosis in childhood will be further lowered. The childhood type of tuberculosis shall become more frequent among adults than at present. In order to develop the adult type of tuberculosis one must previously go through the primary complex and the stages afterward. The allergy must be modified until the peculiar reactivity responsible for the adult type is established.

The prophylaxis of tuberculosis in childhood is more important than the therapy. That the tuberculosis of the members of the family must be prevented is clear. In this respect proper food and housing, plenty of sunshine and fresh air, avoiding of overwork are the real measures against tuberculosis. It is evident that our fight against tuberculosis will be incomplete as long as we permit people to live in slums and starve.

The therapy has as its goal the improvement of the resistance. Bed rest, good food, fresh air and sunshine are the most important of therapy for the nonsurgical part of the disease. Lately more attention is paid to a greater supply of all vitamins. Cod liver oil, vitamins C and D, abundance of fresh fruit, fresh vegetables (especially raw vegetables) are recommended. In the last years the pneumothorax treatment even of the postprimary stages of childhood tuberculosis was advocated. I find rarely a case with strict indication. The prepuberty and puberty form of adult type of tuberculosis frequently needs pneumothorax treatment and sometimes thoracoplasty. The results are unfortunately not so satisfactory as in later periods of life. This is mostly due to the fact that the cases come to treatment in an advanced state of the disease. Frequently the process is bilateral. However, we have treated over 90 cases with pneumothorax, some of them with very good results.

CLINIC OF DR. DAVID ULMAR

SEA VIEW HOSPITAL

CLINICAL FORMS OF PULMONARY TUBERCULOSIS: THEIR RECOGNITION AND TREATMENT

CLINICAL experience with pulmonary tuberculosis has amply demonstrated the fact that all cases of the disease do not react alike. While one patient with extensive pathology recovers rapidly and completely, another individual with seemingly slight pathology may just as rapidly progress to extensive or even fatal outcome. Experiences of this sort at the bedside, with resultant confusion of ideas regarding prognosis and treatment and even diagnosis itself, led to serious thought on the part of some of the workers at the Metropolitan and Sea View Hospitals. Out of the hodge podge and chaos was gradually evolved a clinical classification of pulmonary tuberculosis which has now been in use at these institutions for over six years.¹ Actual trial has fully shown that this classification aids in gauging the prognosis and is invaluable in determining the type of therapy to be performed and in evaluating its results. Its simplicity and ease of application warrant its general adoption.

In order to understand the various types of tuberculous reaction in the lung and to intelligently comprehend their evolution, it is necessary first to keep clearly in mind a few simple but fundamental principles. At birth all individuals are completely free of tubercle bacilli. However, at varying intervals from infancy to adult life, practically all persons, especially those living in urban communities, sooner or later come in contact for the first time, with tubercle bacilli. When these

organisms gain entrance, the usual body defense against bacterial invasion is called into play. There is a slight local reaction at the site of inoculation. Many of the invading organisms, however, escape from this focus and are swept along in the draining lymphatics, to be entrapped by and to multiply in the regional lymph nodes. Even this barrier may not be sufficient to block all of the organisms, although in most instances it does suffice. Nevertheless, not uncommonly a few of the organisms may wander further afield, to be filtered out in the body where they may be. The apices of the lungs are especially good filters and some may be stopped there. Others may reach different parts such as kidney, spleen, bone or what not. This casual and haphazard wandering continues for about ten to fourteen days after the first invasion. At the end of this period, a peculiar change occurs in the tissue of the inoculated individual. One of these changes causes a fixation of the tubercle bacilli wherever they may be, so that henceforth free wandering does not take place. From now on, any similar migration is simply a mechanical accident and not a part of the normal, natural evolution of tubercle. Another tissue change which seems to occur at this same time is an alteration in the sensitivity of the tissue cells to the tubercle bacillus and its products. Whereas formerly the body was not at all sensitive, or allergic, to tubercle bacilli, now it is extremely allergic and reacts violently to minute doses of the tuberculous antigen. The positive tuberculin reaction, which now appears for the first time, is an index of this new sensitivity. In a similar manner, wherever there are deposits of tubercle bacilli in the body this allergic reaction will take place, the most violent reactions, of course, being found where the bacilli are present in the largest numbers. It is, therefore, not unnatural to find a very large zone of inflammation in the regional lymph nodes. Inasmuch as the commonest portal of entry is the lung, the hilum nodes, in such a case, may be tremendously swollen. This condition is sometimes erroneously designated "hilum tuberculosis." It is emphatically not hilum

erculosis, but rather the regional lymph-node involvement of a primary complex whose portal of entry is in the lung. It is not the purpose today to discuss the primary infection, most of which recover without incident. We shall confine ourselves to the reinfection type of pulmonary tuberculosis and the clinical forms which it may assume.

In the reinfection form of tuberculosis, the type that is practically always seen in adults, the inoculation of organisms takes place in a tissue whose reaction has been altered as described above by the previous primary infection. As a result of this change, there is no longer the migration of organisms to the regional lymph nodes. Therefore, they are not grossly enlarged—an important point of differentiation between the primary and reinfected types of infection. But, in addition to this localizing effect, there is also present, as was mentioned before, an increased sensitivity or allergy response, which plays a large part in determining the clinical form of the ensuing tuberculosis. There is considerable variation in the sensitivity of different individuals to tubercle bacilli. Just as some people are sensitive to the pollen of ragweed and, therefore, have hay fever, while others are not—so are some people sensitive to tubercle bacilli, and others relatively less so. Another way of viewing the situation is to state that the threshold level of stimulation of the sensitivity response in the very sensitive individual is low, while in the relatively insensitive individual, it is high. The corollary to this is that the sensitivity response can always be stimulated, provided there is a sufficiently large dose to reach the threshold level. This is exactly what we see clinically. There is, therefore, added another factor, namely, dosage, to the sensitivity response as the predominating influence in determining the clinical form of the ensuing tuberculosis. Depending upon this interplay between allergy and dosage will depend the clinical type of disease.

For the sake of simplicity, the clinical forms of pulmonary tuberculosis may be divided into two main groups: exudative and nonexudative or productive. The exudative forms occur

in the relatively sensitive group of individuals or those who have been subjected to high dosage. The productive forms occur in the relatively insensitive group who have been subjected to small dosage. We shall discuss first the exudative group.

Benign Exudative Tuberculosis.—Let us suppose that we have an individual who is very sensitive or allergic to tubercle bacilli and that that individual aspirates a minute quantity of tuberculous antigen. Wherever in the bronchial tree system that this dose lodges there will be produced an immediate violent inflammatory reaction, with an outpouring of serum and fluid in all directions. The broncheolar and alveolar walls will become inflamed and edematous. There

Fig. 47.—From the focal point of inoculation, there has been an inflammatory edema in centrifugal direction.

will be an outpouring of fluid into the alveoli themselves. A glance at Fig. 47 illustrates what has occurred.

The aspirated dose, however, has been small. The pulmonary tissue, while stimulated and irritated, will not be over-irritated to the point of cell death. Therefore, if no further aspiration takes place, the tendency is for a return to normal. The exudation absorbs and normal lung tissue remains.

The clinical picture of this form of tuberculosis, which we can call the benign exudative type, corresponds with our theories of pathogenesis. As can be expected with anyone who is acutely sensitive to allergic stimulation, the patient, after aspiration of the tuberculous material, becomes suddenly ill. There are all the general symptoms of any toxic state such as fever, rapid pulse, malaise and other general symptoms in-

dicative of an acute infection. The severity of these symptoms will depend on the extent of the reaction and may vary from hardly any deviation from normal, as in the case of very minimal lung reaction, to severe prostration, as may be seen with extensive pathology. In addition to these general symptoms, there are also present the localizing symptoms due to the lung irritation. There is a slight cough and slight expectoration. In some instances, there may be actual blood spitting, varying in amount from mere streaking to copious hemorrhage. This latter symptom occurred in 43 per cent of one of our series.² Characteristically, however, all symptoms quickly subside, so that within a week or two the patient feels perfectly well and considers that he has recovered from nothing more serious than an ordinary cold.

Physical examination of the lungs does not reveal any startling findings. Possibly there may be slight dulness over the affected part or slightly diminished intensity of breathing. Occasionally there may be heard a fine, high-pitched râle. As often as not the physical signs are apt to be within normal limits. It is only when one fluoroscopes the patient or looks at the x-ray of the chest that one is amazed at the extent of the pathology. Out of all proportion to the scant physical findings or the apparent good health of the patient is seen a more or less homogeneous exudative shadowing of varying size. It may be present in any portion of the lung field, from apex to base. Regardless of its extent, it is quick in its appearance and may disappear almost as quickly. One patient, who had a positive sputum, had complete x-ray clearing in ten days. Usually, however, a longer period is required; two or three months perhaps. Complete clearing of the exudative reaction, as far as can be determined clinically, does occur, so that finally the patient is back to the starting point again. Where the benign exudative reaction was due to an exogenous source, this means that the patient has returned to a normal lung. Where the spill has taken place from some other focus within the lung, this original focus may remain, while the new exudative reaction clears.

Sputum examination, unless done right at the start of the illness, is usually futile for the simple reason that there is no sputum after the first few days. Tubercle bacilli are difficult to demonstrate, but may occasionally be found if diligently searched for at the onset of the disease.

The treatment consists simply of rest and the avoidance of further contact with tubercle bacilli. This means protec-

Fig. 48.—x-Ray of a thirty-year-old woman who complained of right-sided pleurisy three weeks previously. All symptoms had disappeared at the time this picture was snapped. Notice the extensive exudative reaction.

tion from the open case of tuberculosis. All members of the household must be carefully examined, to make sure that the contact is not at home. If the patient is admitted to a sanatorium, it must be remembered that as far as this patient is concerned, tuberculosis is as acute and infectious as is scarlet fever. Isolation procedures should be followed as much as possible. These patients recover if left alone.³

I present the following case to illustrate this type of tuberculosis:

B. T., a thirty-year-old female, three weeks before being seen by us had a pleurisy on the right side. She remained in bed two weeks at the end of which time all symptoms had disappeared and the patient returned to work. Because of a rule of the employer's medical department, which automatically referred for consultation any person who, due to pulmonary symptoms, stayed

Fig. 49.—Same case as Fig. 48 twenty days later. Note the extensive resolution of the shadowing.

home for three or more days, this girl was seen by us. There were no symptoms whatsoever. The patient's general appearance was excellent. Physical examination of the chest revealed altered breathing over the upper half of the right chest. There was slightly diminished breathing at the right base, with a few fine râles anteriorly. x -Ray taken at this time is shown in Fig. 48. Notice the extensive shadowing. On nothing more than simple rest, the progress was shown in Fig. 49, taken two months after the original film. She has now returned to work seven months after the original picture was taken.

Caseous Pneumonic Tuberculosis.—We have just seen the result where a sensitive individual aspirates a small dose of tuberculous material. Let us now consider the outcome when a large dose is aspirated. Here we have the same allergic stimulation of lung tissue as was seen in the first type. However, because of the large dose of tuberculous antigen, the lung tissue, instead of being merely slightly irritated and stimulated, is overirritated by the excessive allergic stimulation, to the point of cell death. We are now no longer dealing with viable lung tissue, which tends to return to normal, as in the previously described form, but rather with an area of lung gangrene, so to speak, which cannot return to its previous normal state. The whole affair is quite analogous to the Mantoux reaction, where too large a dose is injected and vesiculation or ulceration ensues. Once cell death is established, repair can only take place in the same way as repair occurs following gangrene anywhere else in the body. The necrotic tissue must first be sloughed away, after which the reparative scarring predominates. This is what we also see in the lung that has been overirritated to the point of destruction or caseation. The caseous material is sloughed away and leaves a hole or cavity behind, in place of the previously existing lung tissue. Reparative scar tissue now heals the stump. In other words, the cavity is lined with this scar tissue. As far as that particular phase of the disease is concerned, the patient is cured. Unfortunately for the patient, the scar which lines this cavity is not normal healthy scar, but, usually, tuberculous scar. As we shall see later, this is of most serious import to the patient. This form of exudative tuberculosis, which goes on to caseation and antrum formation, we may designate "caseous pneumonic tuberculosis."

The symptomatology of the patient with caseous pneumonic tuberculosis is quite similar in its onset to the resolving exudative form. Unlike the benign exudative, however, the symptoms of the caseous pneumonic persist. As softening and sloughing of the caseous area takes place, there may be considerable expectoration, which is always loaded with tubercle

bacilli. Gradually, the caseous material is coughed up and expectorated. As this takes place, the expectoration gradually diminishes, although it usually never completely disappears. Characteristically, the sputum in the caseous pneumonic form is always loaded with tubercle bacilli, even after the acute phase has passed. This is so because of the fact that the reparative scar is a tuberculous scar from which there is a constant breaking down of tubercle and shedding of bacilli into the cavity. With the expectoration of the original caseous area, the toxic absorption diminishes so that the patient begins to improve clinically. The temperature gradually subsides, appetite improves, weight gains may be made. The patient may now feel perfectly well again. However, there usually remains slight cough and expectoration. This may sometimes be present only in the morning on arising. As has been said before, tubercle bacilli are always present. It is important to remember that occasionally the true sputum may be unconsciously swallowed, so that no search is complete without examination of the gastric contents for tubercle bacilli.⁴ When the patient has reached this point of comparative well being, the chronic end-stage of the acute caseous pneumonic form of pulmonary tuberculosis has been reached. It is important to remember this point. In the past, this later phase of the acute caseous pneumonic form has been confusingly and erroneously called "fibrocaseous"—"fibro-ulcerative"—"fibro-cavernous" tuberculosis. These various so-called "forms" are merely part of the caseous pneumonic type, although seen in a different time phase.

The physical signs of the caseous pneumonic form, in contradistinction to the benign exudative type, are usually plentiful, especially after softening of the caseous area begins. There is alteration of the normal vesicular breathing to bronchovesicular, broncho-amphoric, or other types of breathing, depending upon the underlying pathology. Râles are usually numerous and may be quite coarse in size. Of course, the detection of altered signs will depend upon whether or not

the pathology is available to this method of search. Deep-seated lesions that are surrounded by normal lung may reveal no evidence on physical examination of their presence.

x-Ray examination of the caseous pneumonic form, on single picture, may frequently be confused with the x-ray of the benign exudative form and has led frequently to gross errors in treatment. The film shows more or less extensive zones of exudation, which may occupy any portion of the lung field. Serial pictures show the basic differences in the two forms. While the benign exudative clears by resolution, the caseous pneumonic clears by sloughing and cavity formation, so that the end-stage shows cavity of varying size and scar. With contracture of this scar and perhaps other mechanisms, there is shifting of mediastinum and trachea, such as is seen in no other type of tuberculosis.

As might be expected with a process of this sort, various complications can occur. If the pneumonic process is sudden and extensive enough, there may be symptoms of rather severe anoxemia with cyanosis, breathlessness and other evidence of respiratory failure. If the caseation reaches the pleural surface of the lung and sloughs through before there has been opportunity for an adhesion to form between the visceral and parietal layers of the pleura, a spontaneous pneumothorax and subsequent pyopneumothorax will ensue. The constant expectoration of bacilli and swallowing of some of them may produce a tuberculous involvement of the gastro-intestinal tract. This complication was found in well over 50 per cent of our cases. In a similar fashion the larynx may become involved. By far the greatest complication, however, in the caseous pneumonic form of pulmonary tuberculosis is the probability of bronchogenic extension of the disease. No longer need the patient come in contact with anyone else to contract the illness. By means of his own positive sputum, he is his own contact. From an open cavity, no matter how small, the positive sputum can trickle into other parts of the lung to set up new foci of disease. This most serious complication takes

place, sooner or later, in over 90 per cent of the cases. Its prevention constitutes one of the major problems of treatment.

I shall dwell but briefly on the treatment of the caseous pneumonic form of pulmonary tuberculosis. The treatment phase may be divided into two parts: treatment of the acute stage and treatment of the subacute and chronic stages. During the acute stage, it has been our experience that bed rest and symptomatic treatment give the best result, in addition to avoiding the pitfall of overtreating the benign exudative form, which at first glance might seem similar to the caseous pneumonic form, but which clears spontaneously and without active, outside help.

Once the sloughing out process has occurred and the subacute or chronic stage is reached, the problem becomes a mechanical one of closing off the cavity to obtain a negative sputum. Various procedures are used, all of which depend upon a lung collapse mechanism. Pneumothorax, with various adjuvants, if necessary, such as closed pneumonolysis for the severance of adhesions, may be tried. If pneumothorax is unsuccessful because of adhesions, various plastic operations on the chest wall itself may be done to obtain a collapse of the lung. The success of the treatment is gauged solely by the disappearance of bacilli from the sputum. Where the process is bilateral, as frequently happens, the amount of treatment is limited only by the mechanical skill of the doctor and the physiological capacity of the patient.

I present now the following case, which illustrates the caseous pneumonic form of pulmonary tuberculosis:

V. L., a twenty-one-year-old female, was admitted to one of the municipal hospitals with a pneumonia on the right side. She remained in the institution three months and was then discharged. The initial film is shown in Fig. 50 and her discharge film in Fig. 51. Note the clearing, but also note the residual scarring and the small cavity. The sputum was negative for tubercle bacilli, but gastric examination was not done. The patient worked for one year and felt well. Cough and expectoration then reappeared, along with fatigue and loss of weight. Her new x-ray is shown in Fig. 52. Tubercle bacilli were readily demonstrated in the sputum. The patient went rapidly downhill and died.

Fig. 50.—x-Ray of a young woman showing an exudative pulmonary reaction in the upper lobe on the right.

Fig. 51—Same patient as Fig. 50, but three months later. There has been a clinical recovery and a gain in weight. Considerable resolution has occurred. However, note the annular shadow in the first interspace on the right.

This case illustrates what may happen, and usually does happen, to the caseous pneumonic form of tuberculosis, if the cavity is not closed. General good health and weight gain mean nothing, as long as there are any free bacilli in the bronchial tree. It is important to utilize every means at our disposal before we tell a patient that his sputum is negative.

Exudative Productive Tuberculosis.—In addition to the rapidly resolving benign exudative tuberculosis and the malignant exudative or caseous pneumonic tuberculosis, there

Fig. 52.—One year later. Note how there has been a bronchogenic extension of the disease from the small focus in the right apex.

is another clinical type of exudative tuberculosis, which we can term the exudative productive form. In this type, because of the peculiar balance between allergy and dosage, there is produced a form of tuberculosis which is acute and exudative in onset, but in which there is some slight but definite lung destruction. Clearing and resolution of the exudation does occur, but not to the completeness which is seen in the benign exudative. Nor does sloughing and destruction occur to the extent that is seen in the caseous pneumonic group. Rather

is a middle course followed. While extensive resolution takes place, there usually remain some linear strands of scarring in the center of the involved area.

The symptomatology of the exudative productive form follows a similar middle course. The complaints gradually subside; not as quickly as the benign exudative type, but sooner than in the caseous pneumonic form. The sputum, although positive at the start, is never as highly positive as in the caseous pneumonic patient. It soon begins to diminish in amount as well as in bacillary content so that after a few months it may be negative. This is rarely seen normally in the true caseous pneumonic form.

The physical signs correspond roughly to the changes in pathology. At the start, they are not as scant as in the benign exudative type. The altered quality of breathing and moist râles are modified and diminished as resolution progresses. In a similar fashion, the serial x-ray pictures change from extensive, exudative shadowing at the start to a few fibrous strands at the completion of the affair. The whole evolution may last from six to eighteen months.

The following case demonstrates this form of tuberculosis:

V. B., when first seen, gave a history of a chest cold with a productive cough for three weeks and pain in the right chest for one week. On physical examination, there was dulness, harsh tubular breathing and coarse moist râles to the fourth rib. There was a temperature of 102.8° F. and a pulse of 124. Tubercle bacilli were present in the sputum in goodly number. The x-ray appearance at this time is shown in Fig. 53. After seventeen months' sanatorium care all symptoms had disappeared. The sputum was long since negative. There had been a weight gain of almost 50 pounds.

Chronic Productive Tuberculosis.—We have just discussed the exudative forms of pulmonary tuberculosis. We now pass on to the productive type. In this category we are probably dealing with an individual of low sensitivity, who aspirates a relatively small dose of tubercle bacilli. The threshold level of stimulation of the sensitivity response is not reached. Therefore, we do not see clinically any of the acute allergic manifestations which predominated in the other forms.

Fig. 53.—x-Ray of a white adult showing the dense exudative shadowing on the right.

Fig. 54.—Same as Fig. 53, showing the major resolution of the exudative response but with the permanent residual productive scarring.

Rather is there stimulated a slow, proliferative response, without any marked surrounding exudative reaction or lung involvement. The whole affair is very chronic and relatively benign.

This type of pulmonary tuberculosis, which we have termed the chronic productive form, usually starts at an apex and during the course of many years, slowly creeps downward toward the base of the lung. Because of the small dosage and the relative lack of exudative response, the individual lesions are small and discrete and surrounded by relatively normal lung. Occasionally, these individual lesions may coalesce to form larger areas of cirrhosis. At times, caseation may occur in the central portion of these areas and slough out to form a small cavity. When this happens, we are now dealing to all intents and purposes, with a caseous pneumonic form, although its mode of production may be quite different from the acute caseous lesion.

The symptom picture of the patient with the chronic productive form is sometimes very indefinite but at other times very striking. On our hospital services we usually see a patient in the fourth or fifth decade of life, who is admitted complaining of hoarseness or gastro-intestinal disturbance or some other extrapulmonary symptom. Generally, no mention at all is made of any respiratory disorder. It is only when the patient is closely questioned that he recalls a slight cough which he has always had as long as he can remember and a slight morning expectoration, which is usually blamed on smoking. There is generally admitted, too, some shortness of breath on exertion. The chronicity of the disease and the absence of acute allergic manifestations make it easy to understand this situation. Occasionally, however, especially in younger individuals, there may be slight low grade flare ups, with an increase in cough and expectoration, perhaps slight blood streaking and slight rises in temperature. These spikings, in an otherwise relatively smooth course, are probably due to small exudative foci resulting from slightly larger bronchogenic

spills. The patient quickly recovers his previous good health, however, and may continue for an indefinite period before experiencing another similar episode.

The ordinary uncomplicated chronic productive patient raises very little sputum. Tubercle bacilli are hard to find, even on concentration. Usually one positive sputum will be encountered in every ten to twenty specimens. Gastric examinations may sometimes yield the organisms when search of the sputum fails. It is this scarcity of organisms which serves to explain the benign character and the slow spread of this form of pulmonary tuberculosis.

If cavity formation occurs, then expectoration is increased and all the dangers and possibilities incident to the caseous pneumonic type of disease must be watched for. As a terminal affair in many of the advanced chronic productive cases, there seems to be a sudden change in the type of tissue reaction, so that each productive focus becomes an acute caseous focus. The patient becomes acutely ill and from this point on goes rapidly downhill, with cough and copious expectoration that is loaded with bacilli, as is seen in the caseous pneumonic form.

The physical signs in the patient with chronic productive tuberculosis are notoriously scant. The compensatory emphysema which surrounds the small, individual productive nodules readily masks whatever abnormal signs might be produced. Thus, very extensive pathology may be present without yielding any trace of its presence by means of physical signs. Generally, some slight alteration of breath sounds may be detected or a few fine râles heard, especially in the apices. It is the x-ray, however, which gives us the best evidence of the chronic productive form of tuberculosis. In the early stages, the lesion is confined to one or both apices. The shadowing instead of being diffuse and homogeneous, as in the exudative forms, is discrete and nodular, with relatively normal intervening lung. Occasionally, there may be small, acute exudative reactions corresponding with the clinical flare-ups. When these subside, the original productive lesion remains un-

changed. As the years advance and the disease progresses, the nodular shadows gradually creep downward toward the lower lung fields. When the lesion is extensive, almost the entire lung may be studded with these discrete nodules—so much so, in fact, that this type of *x*-ray has sometimes been diagnosed as chronic miliary tuberculosis. Closer inspection, however, will show the apicocaudal extension, with the greatest concentration of nodules in the upper poles of the lungs.

The treatment of the chronic productive form should resolve itself into the treatment of the occasional acute little flare-ups by bed rest and symptomatic treatment, and general supervision of the patient in the interim. The pathology in these patients may or may not slowly progress, in spite of rest and sanatorium care. It is, therefore, almost criminal to confine these patients to an institution for years, merely because serial *x*-rays show increases in pathology, the patient otherwise being perfectly well.

However, one must be exceedingly cautious lest there be overlooked a small cavity at an apex, from which a more rapid bronchogenic seeding of organisms can take place. If such a cavity be discovered, then the remarks concerning the caseous pneumonic form holds true and the patient is treated accordingly. Toward the latter phases of the illness, various complications may arise and must be treated as they present themselves. Not infrequently, a tuberculous meningitis is the terminal complication.

D. F. was first seen four years ago, because of a slight cold of three weeks' duration. There were no abnormal physical findings, the patient looked well; temperature and pulse were normal. She was seen in consultation only because of the *x*-ray picture, which was taken routinely by her employer, because of the cold. Figure 54 shows the appearance of the film at this time. It was felt at that time, that this girl did not have any activity of her tuberculosis. She was accordingly permitted to continue with her work. This patient remained perfectly well till a year and a half later, when she gave a history of having spat up some blood four weeks previously. Two weeks later, pain in the left chest appeared, the temperature became elevated and the patient took to her bed. The pain gradually subsided, but for one week prior to her examination, presented the typical findings of a pleurisy with effusion on the left side, with dulness and diminished to absent breath sounds. The temperature was 99.2° F.

It was felt that this girl had developed an acute pleural effusion, probably the result of a rupture of a small subpleural tubercle, with a discharge of its contents into the allergic pleura. A period of curing was recommended. The patient spent four months following a sanatorium routine, after which she returned to work and has been employed steadily since then. She has felt perfectly well and has had no pulmonary symptoms. Her x-ray series following the absorption of the effusion has remained stationary, except for a recent film, which suggests a slight increase in the shadowing and the possibility of cavitation at the left apex. Sputum examinations were negative for tubercle

Fig. 54.—x-Ray of a twenty-year-old girl, showing the nodular type of shadowing at the apices, especially on the left, typical of the chronic productive tuberculosis.

bacilli. Gastric examination, however, showed the presence of organisms. This patient has been admitted to a sanatorium where pneumothorax treatments will be attempted on the left side in an effort to close the small apical cavity and thus prevent future bronchogenic spread.

This case illustrates the chronic productive type of tuberculosis, in a minimal stage and shows how it may spread insidiously without any noticeable symptoms. It also shows the importance of examining the gastric contents for tubercle bacilli when sputum is not obtained.

To Recapitulate.—For a clearer understanding of the natural history of pulmonary tuberculosis and subsequently a more intelligent application of therapeutic efforts, it is essential that the clinician be well acquainted with the various forms in which the disease may present itself. Depending upon the balance between allergy and dosage, and especially the latter, will depend whether the clinical form of the disease is either exudative or productive. The exudative forms may be one of three different types. There is a rapidly resolving form—the benign exudative. Here there is rapid resolution. The only treatment required is rest and protection from further contact with tubercle bacilli.

The exudative productive also clears by resolution, but not as rapidly or as completely as the benign exudative. Here again, recovery takes place without active intervention. The caseous pneumonic form, on the other hand, ends in slough and cavity formation from which there is a constant shedding of tubercle bacilli, to seriously threaten the remaining parts of the lung. It is this bad mechanical end-result of the caseous pneumonic form which must be energetically treated by the various forms of collapse therapy.

The chronic productive form is much slower in its onset and progress. Over the course of many years, it browses down from apex to base, the patient meanwhile for the most part feeling quite well. Treatment seems to have little effect unless definite cavity is present.

It should be remembered that there may be various combinations of these different forms of tuberculosis in the same individual. Thus, a person with a caseous pneumonic focus at an apex may have a resolving exudative spill into the contralateral lung. Regardless, however, of where the lesion occurs, or in what combination, or whether brought by the bronchogenic or hematogenous route, the principles involved are the same. Massive dosage produces one of the three forms of the exudative reaction. Small dosage causes a productive response. Our judgment must be based not on the quantity

of the disease but on a qualitative analysis. By keeping these few principles clearly in mind, we can more rationally evaluate the case and more logically apply our therapy.

CLINIC OF DR. DAVID REISNER

SEA VIEW HOSPITAL

HEMATOGENOUS TUBERCULOSIS OF THE LUNGS

HEMATOGENOUS tuberculosis of the lungs is frequently thought of as an acute, usually fatal disease and as a part of generalized tuberculous process which is characterized by diffuse and massive dissemination of miliary tubercles throughout the organs. While it is true that this condition is a well established entity, it must be looked upon as representing only an extreme event, that is, a severe generalized infection evidently caused by a sudden and massive invasion of tubercle bacilli into the blood stream. Because of the acute clinical picture and the characteristic pathologic changes, acute miliary tuberculosis has always been regarded as the classical manifestation of a hematogenous tuberculous infection. The various types of chronic generalized forms of tuberculosis and their corresponding pulmonary lesions have not received sufficient attention until recent years. It is now well recognized, however, that hematogenous tuberculous lesions may appear under a multitude of forms and phases with numerous gradations in extent and severity, ranging from very mild, abortive forms, through various intermediary types, to severe and fatal generalizations, as exemplified by acute miliary tuberculosis.

The various forms of hematogenous pulmonary tuberculosis represent in a large proportion of cases a part of a more generalized process. This will be discussed in greater detail later on. The pulmonary lesion, however, lends itself more easily to clinical investigation than the corresponding changes in other organs, as the changes in the lungs are readily demonstrable on radiographic examination. The recognition of the

hematogenous forms of pulmonary tuberculosis, especially of the chronic types, offers therefore an important index in the evaluation of chronic and protracted forms of systemic tuberculous infections.

A classification of hematogenous tuberculosis of the lungs into distinct types is extremely difficult because of a variety of intermediary phases and gradual transitions from one form into another. It would seem helpful, however, for the sake of clarity to postulate the following groups:

I. Diffusely disseminated hematogenous miliary tuberculosis, which may be subdivided into:

(a) Acute forms.

(b) Subacute and chronic forms.

II. Hematogenous forms of chronic pulmonary tuberculosis of varying extent, miliary or nonmiliary in type. This group may be subdivided into:

(a) Uncomplicated chronic hematogenous forms.

(b) Hematogenous forms with complicating bronchogenic progression.

I. DIFFUSELY DISSEMINATED HEMATOGENOUS MILIARY TUBERCULOSIS

As to the acute miliary tuberculosis, a detailed description of its well known clinical features and the corresponding pathological changes must be omitted here. The clinical manifestations may vary according to the preponderance of one or the other group of symptoms, this giving rise to the old established division into the pulmonary, the meningeal and the typhoid form. The average duration of illness from the onset until the fatal termination is generally between two and four, sometimes six weeks. It is important to mention, however, that it is difficult to set down definite time limits, a point which serves to emphasize how arbitrary a separation between acute, subacute and chronic forms of miliary tuberculosis may be. On one hand, there are cases showing a peracute markedly septic course in which the fatal termination may take place even within a few days in some extreme instances. Such cases

have been described under the term "sepsis tuberculosa acutissima," the clinical picture resembling an unusually severe general septicemia. Pathologically, such cases also differ from the usual miliary tuberculosis, inasmuch as no typical tubercles are found in the organs. Microscopically, however, there are found numerous small areas of necrosis which contain abundant acid-fast bacilli. There are, on the other hand, cases of miliary dissemination in the lungs which show a subacute or decidedly chronic course. Among the latter several types may be distinguished.

In some instances the onset may be acute with high fever and pronounced toxic symptoms. The course, however, is not progressive, the acute symptoms subside and the temperature becomes subfebrile or normal. Serial roentgen examination shows that the miliary dissemination throughout the lungs remains unchanged over a period of weeks or months. Eventually, after a prolonged illness, signs and symptoms of meningeal involvement may set in which results in fatal termination.

In other cases one misses entirely an acute phase of the disease, constitutional signs and symptoms are quite inconspicuous. Physical signs over the lungs may or may not be found. In such cases one is usually greatly astonished to find the typical miliary dissemination in the lungs on roentgenographic examination and the diagnosis of miliary tuberculosis is at times viewed with skepticism because of the marked contrast between the roentgen findings and the general clinical aspect of the case. In a number of cases the miliary dissemination in the lungs is preceded by pleural effusion, sometimes recurrent, which may be either uni- or bilateral. This also applies to cases of acute and fatal forms of miliary tuberculosis.

The further course and evolution of the disease in cases of chronic or latent miliary tuberculosis of the lungs does not behave uniformly. Some patients remain asymptomatic and apparently well for an indefinite period. The objective findings in the lungs may show no further change. However, as in the subacute forms, a complicating meningitis is not infre-

quently the eventual cause of death. In other cases metastatic lesions of a localized nature may develop in the peripheral organs, such as in the bones or joints, urogenital tract, serous membranes, sometimes skin or eye manifestations may appear. In such cases it is often difficult to establish, however, whether these lesions were preexistent or whether they followed the pulmonary dissemination. In the absence of such complications these individuals may remain perfectly well and symptom-free, although the pulmonary changes are persistent.

In some cases showing a clinically favorable course, progressive resolution of the pulmonary changes may be observed on serial roentgen ray studies. The process of resolution is usually slow, extending, as it does, over a number of months, or years. The end-result may be either complete or incomplete clearing. The former is more apt to take place in cases showing dissemination of soft foci which often appear larger than miliary size. In other cases there remain residual changes, such as sparsely scattered discrete nodules, with or without calcification, or a more or less diffuse increase in the linear markings due to interstitial fibrosis.

Although doubted for a long time, there are now sufficient observations available to indicate that healing of a hematogenous pulmonary dissemination is a distinct possibility, not only in the clinical but also in an anatomical sense. From an anatomical standpoint complete disappearance of the focal dissemination is quite conceivable, since in a number of instances the hematogenous spread may result in the formation of disseminated small exudative pneumonic foci, miliary alveolitis, and very little proliferative tissue reaction. Such changes are capable of partial or complete resolution. In other instances the healing process consists in transformation of the miliary tubercles into hyaline connective tissue nodules with resulting cicatricial shrinkage. These changes in conjunction with the subsequently developing emphysema account for the fact that such slight residual foci may entirely escape visualization on the roentgenogram. Healing with calcification con-

stitutes, of course, a persistent anatomical change and is easily demonstrable radiographically. In some cases the process of healing may result in the production of interstitial fibrosis

Fig. 54a.—Diffusely disseminated, healed, calcified, miliary tuberculosis. No clinical symptoms; accidental finding. (Courtesy of Dr. George Cole.)

Fig. 54b.—Roentgenograms of a patient with tuberculosis of kidney and multiple lymphoglandular involvement. A, shows disseminated hematogenous tuberculosis in both lungs. Seven months later (B) there was almost complete resolution of the changes.

along the peribronchial and perivascular lymphatics, "lymphangitis reticularis." This may find its expression on the roentgenogram in the form of fine linear strands causing accentuation of the pulmonary markings.

As regards the pathogenesis of miliary tuberculosis, there has been a tendency to view the development of hematogenous spreads as mere accidental occurrences caused by a sudden invasion of bacilli into the blood stream. Gross anatomical alterations, such as perforation of a caseous pulmonary focus into a blood vessel, or ulceration of a caseous tubercle situated in the intima of a vein, or in the wall of the thoracic duct, are considered as the principal sources of hematogenous disseminations. The bacilli may then be distributed either through the pulmonary circuit, through a part or the whole of the general circulation, or both.

There is little doubt that such events may be responsible for the development of acute and massive generalized forms of miliary tuberculosis. But it must also be borne in mind that tubercle bacilli may enter the blood stream by an indirect route without gross mechanical alterations of anatomic structures. There may be a continuous or intermittent discharge of smaller or larger doses of bacilli into the circulation from a variety of sources. The changes resulting from the primary complex probably provide a frequent source of hematogenous involvement. This may originate either in the primary pulmonary focus, but probably more often in the regional tracheo-bronchial lymph nodes. The bacilli may extend into the circulation by way of the lymphatics into the thoracic duct, from these into the large veins, and the right heart. There are, of course, other potential sources of blood stream dissemination, such as, postprimary pulmonary foci, or various latent or manifest caseous extrapulmonary foci. That the anatomical changes resulting from the primary infection serve as an important source of hematogenous dissemination, is indicated by the fact that generalized forms of tuberculosis are considerably more frequent during infancy and early childhood than in later life, the so-called "early generalization." This is probably accounted for by the fact that in its active stage the primary complex harbors tubercle bacilli of sufficient number and virulence to give rise to extensive dissemination of the disease. As the primary lesion undergoes progressive healing such inva-

sions become both less frequent and probably less severe, as far as the resulting spread is concerned.

It is readily seen that there are manifold possibilities and circumstances leading to hematogenous dissemination and the resulting spread will, therefore, vary greatly in its distribution, extent and severity. There can be no doubt, of course, that the dosage of bacilli and their virulence, as well as the anatomical distribution, are of foremost importance and that variations of these factors may to a great extent account for the variable clinical picture and evolution of the disease, as outlined before. In addition to these, however, there are probably other factors, about which we have as yet little exact knowledge, that may either enhance or retard the development of a hematogenous disease process. Variable conditions of specific allergy and resistance or relative immunity, may greatly modify the consequences of invasion of bacilli into the circulation. It is very probable that the mere presence of tubercle bacilli in the blood stream does not necessarily have to cause generalization of the disease. This is indicated by the observation that in the progressive and destructive forms of pulmonary tuberculosis, although there are ample opportunities for invasion of the bacilli into the circulation, acute generalized miliary tuberculosis and meningitis, as well as manifest extrapulmonary hematogenous metastases of chronic nature, represent a relatively infrequent occurrence. This would seem to suggest a certain antagonistic relation between local progression and generalization of the tuberculous process which may be closely related to specific allergy and the state of relative immunity. There are, on the other hand, certain factors of nonspecific nature which by lowering the state of general resistance may serve as predisposing causes for the actual outbreak of generalized tuberculosis. Among these should be mentioned chronic debilitating diseases, such as cancer or the leukemias; intercurrent acute nontuberculous infections; postoperative conditions, puerperium, old age, and others. Such observations offer grounds for the assumption of a latent or chronic protracted tuberculous bacteremia, al-

though it must be admitted that direct bacteriological proof is difficult to establish with our present methods. An overwhelming massive infection will, of course, under any and all circumstances, lead to an acute and fatal spread. However, given a more limited invasion and favorable general conditions, the resulting pathological changes and corresponding clinical manifestations may show great variations, from subacute or chronic types to very mild or latent forms of hematogenous dissemination.

It is essential to point out that the pulmonary dissemination found in the chronic forms of miliary tuberculosis represents in most instances only a part of a generalized process, just as in the typical acute forms, but in a much milder form. In such cases postmortem examination usually reveals evidence of some spread through the organs of the general circulation, such as, scattered tubercles in the liver, spleen, kidneys, adrenals, etc. These changes are often quite inconspicuous in comparison with the pulmonary findings. The anatomic peculiarities of the pulmonary circulation and the fact that the lung acts as a sort of filter for circulating bacilli, probably account for the predominance of the hematogenous dissemination in the lungs. Whatever the source of bacillary invasion, generally speaking, the lungs bear the brunt of the hematogenous distribution to a much greater extent than any other single organ. In some instances, however, the miliary dissemination may be limited to one or more parenchymatous organs outside of the lung and involve the latter to a much lesser extent or not at all. This may be the consequence of invasion of bacilli into a part of the arterial circuit. On rare occasions such limited disseminations in the organs undergo calcification, similarly as in the lungs, and may be demonstrated on the roentgenograms.

Clinical observation and analysis of postmortem findings in cases of chronic protracted forms of hematogenous tuberculosis, suggest that the changes in various organs may occur at successive intervals and that they may be due to repeated

invasions of bacilli into the circulation. The above-mentioned pleural effusions preceding the pulmonary dissemination or the fact that a number of cases of chronic, apparently benign miliary dissemination in the lungs finally develop a complicating fatal meningitis, may well be explained on that basis. It, therefore, seems that the total course of many cases of sub-acute or chronic miliary tuberculosis of the lungs represents a series of successive phases which under unfavorable circumstances may eventually lead to generalization of the disease and fatal termination. On the other hand, in the absence of a progressive spread and grave complications, such as particularly meningitis, clinical recovery is well within the realm of possibility. It is the ever-present danger of a potential generalization which renders the ultimate prognosis of chronic and latent forms of miliary tuberculosis of the lungs so uncertain.

II. HEMATOGENOUS FORMS OF CHRONIC PULMONARY TUBERCULOSIS

The hematogenous forms of chronic pulmonary tuberculosis to be discussed below must be distinguished, on one hand from the typical miliary dissemination, and on the other hand from the common types of lesions which constitute the vast majority of cases of chronic pulmonary tuberculosis. It may be said that these forms occupy an intermediary position between the classical miliary forms and the ordinary chronic phthisis.

Chronic hematogenous pulmonary tuberculosis presents a large variety of types and stages which differ greatly both as to the extent and the morphological characteristics of the changes. The foci are either of the miliary or of the conglomerate acino-nodose type. Still greater are the variations in the extent of the pulmonary changes ranging from few scattered, sometimes calcified nodules in the apices to a diffusely disseminated spread throughout the lungs. There are various intermediary forms, such as involvement of the upper one third, or of the upper halves, or else of the upper two thirds of both lungs. The features which are constantly

present and which may be considered as characteristic for chronic hematogenous forms are as follows: the disseminated

Fig. 54c.—Hematogenous form of chronic pulmonary tuberculosis associated with bilateral pleurisy. The roentgenogram shows bilateral symmetrical discrete nodular dissemination, predominantly localized in the apices and subapical areas; bilateral pleural effusion, more marked on the left side.

Fig. 54d.—Chronic hematogenous tuberculosis of the lungs. Roentgenogram shows bilateral symmetrical nodular dissemination through the upper portions of both lungs; marked emphysema of the basal portions. Clinical symptoms very slight; sputum negative for tubercle bacilli.

character of the lesion; the bilateral symmetrical distribution; the continuous apicocaudate spread, the foci usually decreas-

ing in size and in number from apex to base; finally, the discrete nodular character of the foci which are of the predominantly productive type. Recurrent unilateral or bilateral pleural effusions are not infrequently associated with these types of chronic pulmonary tuberculosis and must be regarded as a manifestation of hematogenous involvement (Figs. 54c and 54d).

Roentgen examination is of paramount importance in the detection of these lesions. Clinically, in a large proportion of the cases the existence of pulmonary changes is not suspected. They are occasionally discovered on routine roentgenographic examination. This is due to the fact that clinical signs and symptoms are often either entirely absent or extremely slight. Physical examination of the lungs frequently reveals very few abnormal findings, sometimes signs of emphysema or bronchitis. The disproportion between the paucity of clinical signs and symptoms referable to the lungs on the one hand, and the objective changes as revealed on the roentgenogram, on the other, is a striking feature of the chronic hematogenous pulmonary tuberculosis. As a rule, no tubercle bacilli are found in the sputum, in some instances a small number of bacilli may be present occasionally in a large series of concentrated specimens.

An impressive feature of typical hematogenous forms of chronic pulmonary tuberculosis is the absence of gross areas of infiltration, of ulceration and excavation. This is in distinct contrast to the common bronchogenic forms of chronic pulmonary phthisis which are characterized by the presence of these very changes. However, a strict differentiation between chronic hematogenous and bronchogenic forms may often be quite difficult since in a considerable proportion of cases of originally hematogenous lesions, the characteristic features become greatly altered as a result of superimposed bronchogenic involvement. A gradual breaking in of interstitial foci into the air passages evidently accounts for the development of such combined forms. This occurrence naturally opens the way for further bronchogenic progression with ul-

ceration and cavity formation. Clinically this complication manifests itself by the appearance of signs and symptoms of activity and positive sputum. Radiographically there will be found larger coalescent infiltrative foci, in addition to the discrete nodular dissemination, as well as cavity formation. The presence of the latter is at times difficult to determine from the roentgenogram because of their small size, the diffuse pulmonary changes and the frequently present emphysema.

Occasionally the cavities found in connection with chronic hematogenous lesions are of a peculiar appearance, thin-walled, either single or multiple. These cavities are often referred to as the "punched-out" variety and it is assumed by some that they represent a part of a hematogenous process. It should be mentioned, however, that the pathogenesis and the mechanism of development of these cavities has not been sufficiently clarified as yet.

In many cases one may find evidence of superimposed bronchogenic progression in the upper pulmonic fields, while the more dependent portions retain the discrete nodular dissemination. This, in conjunction with the symmetrical distribution of the lesion indicates the hematogenous character of the original process. In other instances, however, the changes resulting from the secondary bronchogenic spread may become the predominant feature of the lesion to such an extent that it is extremely difficult, if not impossible, to determine its original character, unless one has had an opportunity to follow the evolution of the process by means of serial roentgenograms. Occasionally the complicating bronchogenic involvement may cause little progressive and destructive changes showing instead a marked tendency to fibrous tissue formation. The eventual picture found in such instances is a bilateral, symmetrical, cirrhotic-indurative process involving predominantly the upper lobes, often associated with numerous small bronchiectases and marked compensatory emphysema of the lower portions of the lungs. Clinically these cases frequently show a stationary course over a period of many years, in spite of persistently positive sputum.

The pathogenesis of this group of chronic hematogenous pulmonary tuberculosis is essentially governed by similar principles as those outlined in connection with the various forms of miliary disseminations. The differences between these two groups concern largely the extent of the lesion, its morphological character and the course. Because of the more limited extent of the pulmonary lesion, its exceedingly chronic duration and the added secondary changes, there may often be only a distant resemblance between the chronic hematogenous forms and the typical miliary dissemination, as far as the character of the pulmonary findings is concerned. The significant point, however, is the fact that the hematogenous group of chronic pulmonary tuberculosis represents to a large extent a part of a chronic generalized process. In a considerable proportion of cases these types of chronic pulmonary lesions are found in association with various forms of extrapulmonary metastatic manifestations, such as, tuberculosis of bones and joints, of the urogenital tract, the serous membranes, generalized lymphoglandular involvement and others. The frequent coexistence of extrapulmonary hematogenous involvement and pulmonary lesions of the type here described is an important indication of their hematogenous origin. A recent study revealed that about two-thirds of the pulmonary lesions found in association with extrapulmonary involvement, presented characteristic features of the hematogenous group. It must be borne in mind, however, that chronic pulmonary lesions of an identical character are often enough found in cases which present no evidence of manifest metastatic foci elsewhere. Conversely, there may be extensive extrapulmonary tuberculosis without any evidence of pulmonary changes other than the old primary complex. These differences in the localization of the hematogenous spread are probably determined by a number of factors. The anatomic position of the source of bacillary discharge, as discussed in a preceding paragraph, variable organ susceptibility, as well as mere chance location may all be responsible to a greater or lesser extent.

It will be found, however, that although the predominant

lesion may be limited to one or several organs, there is usually also evidence of some distant dissemination. In many cases of chronic and progressive extrapulmonary tuberculosis the pulmonary changes are merely in the nature of an incidental finding, such as sparsely disseminated nodules. Similarly post-mortem examination reveals that almost all cases of hematogenous involvement of the lungs, although showing no clinical evidence of extrapulmonary lesion, present some dissemination in other organs which is often purely abortive in character. From a clinical standpoint such cases may be regarded as chronic isolated hematogenous tuberculosis of the lungs.

The ultimate fate and hence the prognosis of chronic hematogenous forms of pulmonary tuberculosis is largely determined by their inherent tendency to progressive hematogenous propagation of the disease, a point already emphasized in connection with the atypical forms of miliary tuberculosis. Though the pulmonary lesion may appear quite harmless one must always keep in mind the possibility of some unpredictable developments, such as, various metastatic lesions of chronic nature, especially skeletal and genito-urinary involvement, meningitis and acute generalized miliary dissemination.

The differential diagnosis of acute and chronic forms of hematogenous pulmonary tuberculosis should, of course, consider a variety of other pulmonary lesions of a disseminated character, such as diffuse carcinomatosis, pneumoconiosis, diffuse bronchiolitis, chronic vascular stasis, disseminated non-tuberculous miliary bronchopneumonia and disseminated bronchogenic tuberculous spreads. The diagnostic features of these lesions cannot be discussed here in detail. A few words must be said, however, regarding the diffuse focal bronchogenic tuberculous dissemination, which usually occurs following hemoptysis. The differentiation from hematogenous dissemination rests on the history of a preceding recent hemoptysis. The presence of an infiltrative and usually excavating lesion in the lung, the lack of uniform distribution of the changes and the variable size of the foci, are points in favor of a posthemoptysis spread. A consideration of the general

clinical aspects and of the physical findings in the chest, which are as a rule more pronounced in cases of posthemoptysis spread, will also aid in the differentiation between hematogenous and bronchogenic dissemination.

As regards the treatment of the various types of chronic hematogenous pulmonary lesions, it must be pointed out that in a considerable proportion of such cases it is the extrapulmonary process which demands the sole therapeutic attention, as the pulmonary changes frequently represent only an incidental finding. Many cases in which the hematogenous lesion appears confined to the lungs and is limited in extent require no particular treatment and are not in need of institutional care. Such cases may lead a perfectly normal life over a period of many years. Of course, periodic examinations are essential, because of the possibility of activation and progression of the pulmonary lesion and in view of a potential extrapulmonary spread. Other cases, showing more extensive spreads, require prolonged rest treatment with a proper hygienic, dietetic régime. Cases in which the original hematogenous lesion is complicated by superimposed bronchogenic progression and cavitation require active treatment. Collapse therapy is quite difficult in such cases as the disease is invariably bilateral. If the process is not too extensive, the application of bilateral artificial pneumothorax should be seriously considered. However, the marked chronicity of the pulmonary lesion and the frequent pleural involvement resulting in obliteration of the pleural spaces, very often preclude a successful pneumothorax treatment.

CLINIC OF DR. GEORGE G. ORNSTEIN

SEA VIEW AND METROPOLITAN HOSPITALS

MANAGEMENT OF FAR ADVANCED TUBERCULOSIS

PNEUMOTHORAX is not only universally accepted, but has become the principal mainstay in the treatment of pulmonary tuberculosis. Whereas, a decade ago, the treatment was reserved as an emergency measure, today, pneumothorax is urged as soon as a diagnosis of cavity is made. There is still a large number of physicians who believe that all patients should be given a period of rest with the hope of spontaneous resolution of the tuberculous disease. We have found that in the caseous pneumonic forms of tuberculosis, spontaneous resolution with disappearance of tubercle bacilli occurs only in a small percentage of cases (15 to 20 per cent), and that there is a greater possibility of progression of the disease. In discussing the caseous pneumonic tuberculosis we refer to that malignant form of the disease described by Ornstein, Ulmar and Dittler.¹ In brief, "caseous pneumonic tuberculosis" is the open cavity case; the cavity is usually demonstrable in the x-ray, and tubercle bacilli are easily identified on examination of the sputum. In the past, little attention was paid to x-ray and positive sputum, provided the patient was free of toxic symptoms and had added considerable weight. We have learned by bitter experience that fat patients with positive sputum who are considered "temporarily safe," usually die in a few years because of a spread of the disease.

Pneumothorax, therefore, is now indicated whenever a diagnosis of cavity is made. This treatment is used chiefly in unilateral cases of tuberculosis, and is also used in bilateral

cases where the preponderance of the disease involves one lung. In the above types, the results have been both satisfactory and sufficiently gratifying to influence every sanatorium throughout the country to adopt the use of pneumothorax in pulmonary tuberculosis.

It was but a natural step for a group of more intrepid workers to gaze upon the advanced bilateral forms of pulmonary tuberculosis and believe that pneumothorax might be applied with some hope of success.

Fig. 55.—An x-ray of a patient with bilateral pneumothorax. The cavities in both upper lobes are prevented from closing by multiple adhesions. Sputum positive for tubercle bacilli.

At the Metropolitan and Sea View Hospitals, a small number of cases was selected for bilateral pneumothorax. The chief difficulty to face in bilateral pneumothorax was the problem of sufficient lung ventilation. It was also found that in the advanced case, more adhesions were usually present than in the unilateral case. Because of the adhesions, the normal uninvolved lobes were collapsed with the diseased portions of the lung. The patients became dyspneic, and because of the anoxemia, were depressed and irritable. Peculiarly, even with complete rest in bed, where there is anoxemia there is a pro-

gressive loss of weight. In cases with no complicating adhesions, selective collapse of the diseased areas was obtained with no symptoms of anoxemia.

We realized that if the adhesions could be severed, we might obtain the desired selective collapse of the diseased lung and the compressed atelectatic normal lung tissue could be re-

Fig 56.—x-Ray of the same case as Fig. 55. A closed pneumonolysis was done on both sides. Note the complete closure of the cavities in both upper lobes. Sputum negative for tubercle bacilli.

expanded. However, we were fearful about the reaction of the patient to closed pneumonolysis with both lungs partially collapsed, but were pleasantly surprised to find how comfortably the operation was tolerated. After the diseased area was collapsed and the normal lung tissue reexpanded, a closed pneumonolysis was tried on the contralateral lung. Figure 55 is an example of an unsuccessful bilateral pneumothorax in

advanced pulmonary tuberculosis. Figure 56 is an x-ray of the same patient following a bilateral closed pneumonolysis.

With the help of the surgical service we now have a means of controlling the advanced bilateral pulmonary tuberculous disease. Closed pneumonolysis is not a simple procedure in the advanced disease. The adhesions must be severed if we are to have any hope of success. Whereas in the unilateral case the surgeon should take no risk with closed pneumonolysis, in the bilateral case he must have the courage to "go the limit" in severing difficult adhesions. In the unilateral case there is no reason for risking a spontaneous pneumothorax and complicating empyema, because a thoracoplasty could easily control the tuberculosis should pneumothorax fail.

Difficult adhesions have been successfully cut by a combination of blunt dissection and cautery. And in our institutions under the stimulating influence of Dr. Pol N. Coryllos, the surgical staff has become very adept in the handling of these wide and difficult adhesions. In some cases as many as seven adhesions are severed at one time, while in other cases as many as four different attempts at closed pneumonolysis have had to be made before the adhesions have been successfully cut. It is safer to do a little at a time and try again, than do too much in a difficult case. As our experience increased, we decided that by following a definite pattern we might be more successful and produce less anoxemia, than by a "hit-and-miss" method.

The anoxemia could be avoided by obtaining a selective collapse of the diseased portion of the lung without sacrificing normal lung tissue. We decided to do one lung at a time, which would prevent a marked decrease in vital capacity. Our experience was not favorable to simultaneous collapse of both lungs. There was both more chance of anoxemia and less chance for successful closure of cavities. The pattern, therefore, was to start with the more involved side. If adhesions were present, within two or three weeks, or as soon as there was enough space to introduce the thoracoscope, a closed pneumonolysis was to be attempted. The adhesions were to

be severed, the diseased areas of lung collapsed and the normal lung tissue reexpanded to its fullest extent. With the collapse of one lung the contralateral lung was to be collapsed in a similar manner.

Fig. 57.—x-Ray of an advanced bilateral pulmonary tuberculosis. Note the diffuse distribution of the tuberculosis and the multiple cavities in both lungs.

The following is a typical example of the method we have adopted in the treatment of advanced bilateral pulmonary tuberculosis:

A young white female, twenty-six years of age, had been on the wards of the Metropolitan Hospital for sixteen months. Her tuberculosis was so far advanced that the visiting staff had decided that there was very little hope for improvement even with the use of pneumothorax. They believed that if both lungs were collapsed there would be insufficient vital capacity to carry on. Her sputum was laden with tubercle bacilli. Figure 57 is an x-ray of the lungs of this patient taken on March 13, 1935. The case was presented to the surgical conference, and it was decided there to collapse the left lung first

If, after induction of pneumothorax, adhesions complicated the pneumothorax, they were to be cut by closed pneumonolysis. Whatever normal lung tissue was present was to be reexpanded at once, and a similar procedure followed on the contralateral side.

A primary pneumothorax on the left was started on March 25, 1935. We soon decided that the pneumothorax would not be successful because of adhesions to both the upper and lower lobes. On May 2, 1935, Dr. Coryllos did

Fig 58—See Fig 57. A pneumothorax was induced on the left. Because of multiple adhesions to the upper lobe an exploratory thoracoscopy was performed and all adhesions to the upper lobe severed. Note the selective collapse of the left upper lobe. Note the large cavity in the apex of the left lower lobe. Another exploratory thoracoscopy was done and a large adhesion severed with closure of the cavity in the apex of the left lower lobe.

an exploratory thoracoscopy, and successfully severed seven adhesions to the upper lobe. The left upper lobe collapsed, but because of a long adhesion to the apex of the lower lobe, a large cavity still remained open (Fig. 58). On June 17, 1935, Dr. Coryllos again did an exploratory thoracoscopy and was successful in severing the remaining adhesion. Pneumothorax was so managed that the diseased lung was collapsed and the normal uninvolved tissue allowed

to reexpand (Fig. 59). Because the disease involved both lobes of the left lung, the whole lung had to be first collapsed to close the cavities. When the cavities were closed, the normal lung tissue was allowed to reexpand. This occupied almost five months. We then decided to collapse the contralateral lung. On October 3, 1935, a pneumothorax was induced on the right side. Again, adhesions prevented a complete collapse of the right upper lobe. Figure 60 demonstrates the many adhesions preventing the collapse of the right upper lobe. On December 5, 1935, Dr. Coryllos did an exploratory thoracoscopy. Two adhesions were severed with a successful collapse of the right upper lobe. From

Fig. 59.—The left thorax is on the reader's left hand side. See Figs. 57, 58. Note the reexpansion of some of the uninvolved portion of the left lung.

then on, the patient's sputum was free of tubercle bacilli. Figure 61 is an x-ray taken before the patient was discharged to the out-patient department where she receives a weekly refill. Notice the complete collapse of the involved areas of both lungs and the good expansion of the healthy lung tissue. There is only a small amount of effusion on the left side. There was no evidence of anoxemia. Here, we have an example of what can be done with a hopelessly advanced case of tuberculosis involving both lungs—sputum rendered free of tubercle bacilli in less than nine months, and with a good chance of its remaining free of bacilli.

An analysis of our results at the Metropolitan Hospital prophesy a more hopeful future for the advanced case. In 48 cases there were 27, or 56 per cent, in which a negative sputum was obtained. Twenty-one, or 44 per cent, still have

Fig. 60.—See Figs. 57–59. The left lung is on the reader's left hand side. The disease in the left lung has been controlled. A pneumothorax is induced on the right side. Note the partial collapse of the right upper lobe. Multiple adhesions prevent the collapse of the right upper lobe. The sputum is still positive.

a positive sputum or have died. This group includes 15 deaths. An analysis of the deaths is as follows:

- 1—Empyema.
- 1—Miliary tuberculosis
- 1—Cardiac death.
- 1—Tuberculous meningitis
- 2—Severe hemoptysis.

- 2—Extensive intestinal tuberculosis.
- 2—Unsuccessful closed pneumonolysis—the adhesions could not be severed, and the disease spread.
- 5—Extensive bronchogenic spread of the disease.

Fig. 61—See Figs. 57–60. The left lung is on the reader's left hand side. Note the complete selective collapse of the right upper lobe after severing two adhesions by a closed internal pneumonolysis. All the diseased areas in both lungs are controlled. The sputum had been free of tubercle bacilli for over three months when this x-ray was taken. In nine months a hopelessly advanced case has been transformed into a case with a very hopeful future.

Twenty-six cases, or 54.1 per cent, of the 48 required either a unilateral or bilateral closed pneumonolysis.

Unilateral closed pneumonolysis cases, 17:

Negative sputum	11
Positive sputum	6

Bilateral closed pneumonolysis cases, 9:

Negative sputum	3
Positive sputum	6

Out of the positive sputum cases there were two in the unilateral pneumonolysis group and two in the bilateral pneumonolysis group with sputum positive only on concentration. Few bacilli were seen on examination of the concentrated sputum. The patients were clinically improved. It has been the custom at both the Metropolitan and Sea View Hospitals to accept only a negative sputum as evidence of control of the disease.

Spontaneous pneumothorax occurred in 8 patients. All recovered except one, listed as dying of an empyema. In one patient spontaneous pneumothorax happened on three different occasions with recovery. In another patient this unpleasant complication occurred twice with recovery.

When we compare the above results with the figures of Barnes and Barnes,² who reported over 80 per cent deaths within a year after admission to the sanatorium in cases with a less severe form of pulmonary tuberculosis, we must accept bilateral pneumothorax supplemented by closed pneumonolysis as a definite advance in the management of the far advanced case of bilateral pulmonary tuberculosis. The death rate in this group is only 31.2 per cent, compared with 80 per cent of Barnes and Barnes, and 56 per cent of our group have persistently negative sputum.

An analysis of the Sea View group is as follows:

	<i>Negative sputum.</i>	<i>Positive sputum.</i>	<i>Died.</i>	<i>Total.</i>
1933.....	2.0	2.0	0.0	4
1934.....	9.0	6.0	5.0	20
1935.....	12.0	11.0	13.0	36
1936 (Jan. to June)...	6.0	4.0	8.0	18
Total.....	29.0	23.0	26.0	78
Percentage.....	37.2	29.5	33.3	100

An analysis of the combined 126 cases:

	<i>Negative sputum.</i>	<i>Positive sputum.</i>	<i>Died.</i>	<i>Total.</i>
Total.....	56.00	29.00	41.00	126
Percentage.....	44.44	24.02	32.54	100

In the bilateral advanced pulmonary tuberculosis in which collapse therapy through pneumothorax is not possible because of an adherent pleura, there is still the possibility of employing other surgical procedures. We would refer the reader to a recent article by Coryllos and Ornstein³ on the surgical management of bilateral cavernous pulmonary tuberculosis.

When one lung can be controlled by pneumothorax, a thoracoplasty may be attempted on the contralateral side. These authors in selected cases have used bilateral thoracoplasty for the control of bilateral tuberculosis.

SUMMARY

An attempt has been made to present a method of control of the advanced case of bilateral pulmonary tuberculosis. The results obtained prophesy a more hopeful prognosis in the arrest of the disease in the advanced case of bilateral pulmonary tuberculosis.

CLINIC OF DRS. ARTHUR J. GREENBERGER
AND MONROE E. GREENBERGER

SEA VIEW HOSPITAL

UROGENITAL TUBERCULOSIS ASSOCIATED WITH
PULMONARY TUBERCULOSIS

IN our experience, both clinically and at autopsy, genito-urinary tuberculosis is associated with pulmonary involvement. This fact is readily understood when you consider that out of 1650 patients at Sea View Hospital 1400 have been hospitalized chiefly because of pulmonary involvement. Reports by Young and others reveal definite involvement of the lungs and pleura in only 28 to 40 per cent of the cases of urological tuberculosis.

RENAL TUBERCULOSIS

It is our opinion and it is generally conceded that the kidney is first invaded in tuberculosis of the urinary tract. Tubercle bacilli gain entrance by way of the blood stream. We have never noted a case of isolated renal tuberculosis. In a series of 500 postmortem examinations that we reported in June, 1934, 484 of the cases came to autopsy because of pulmonary tuberculosis and only 16 due to extrapulmonary tuberculosis.

In a general hospital about 30 per cent of all nephrectomies are performed because of an underlying tuberculosis. Wildbolz reports 55 per cent of his nephrectomized cases well after ten years, whereas 58 per cent treated medically died within five years. Persson showed that 85 per cent of the cases treated medically died within five years.

Medlar is of the opinion that the disease is always bilateral; in his animal experiments the lesion appeared bilaterally in

88 per cent. Folsom called attention to the fact that the renal tuberculosis produced experimentally by Medlar does not correspond to the chronic renal tuberculosis as seen by the clinician. Likewise the tuberculous areas found by him in the kidneys at autopsy are often manifestations of a terminal miliary tuberculosis. Of the 500 cases in our series in which necropsy was performed, 252 showed evidence of tuberculous infection. Miliary tubercles were found in 228, or 45.6 per cent. By this we mean small tubercles that can be recognized grossly. Microscopic examination of these sections revealed that they vary from necrotic areas to fibrotic tubercles. In this group we found the disease to be bilateral in 82 per cent. We called attention at that time, that in the terminal stage of pulmonary tuberculosis, hematogenous dissemination of tubercle bacilli is a frequent occurrence and gross and microscopic tubercles can be found in the liver, spleen and kidneys. These areas of tubercle formation found at the necropsy table are not to be regarded as evidence of a previously existing clinical tuberculosis, but as a phase of the terminal generalization from another organ tuberculosis, usually pulmonary. It is probable that this explains the unusually high percentage of miliary tuberculosis found in our series and reports of other investigators. Clinically, this type of renal infection is of little significance. It rarely is accompanied by urinary symptoms, has no evidence of pyelographic changes from the normal and is demonstrable only at postmortem examination. This type is commonly referred to clinically as the nondestructive, closed lesion. Organ tuberculosis is the pathologic condition most frequently encountered by the clinician. It is the type of lesion that shows definite pyelographic changes and is clinically recognizable. In our autopsy series only 4.8 per cent of the cases revealed destruction of the kidney substance. It is our thought that most of the arguments and differences of opinion between pathologist and urologist as to whether a case should be treated medically or surgically are based on the fact that the pathologist thinks in terms of the very common miliary

nondestructive lesion, whereas the surgeon knows renal tuberculosis only as the destructive organ lesion. In other words the laboratory worker has been talking about an entirely different entity than the clinician.

The clinical picture of renal tuberculosis, unfortunately, has very few distinctive symptoms and usually not until the ureter and bladder become involved is attention focused in that direction. In any case of persistent bladder irritation, and especially in a young person, one must consider renal tuberculosis. It should be considered gross negligence not to investigate a patient who suffers with persistent frequency and dysuria. A careful check of the history charts on our cases revealed that 60 per cent of the cases with renal involvement presented some evidence of urinary disturbances surprisingly mild as compared to the pathological changes found. This fact must stand out boldly to all of us—and in private practice one must ever be alert and suspect genito-urinary tuberculosis until it is definitely ruled out. At Sea View with 1650 patients our routine procedure allows very few cases to escape our attention. All urines that reveal pus or blood are referred to the resident urologist even though the patient may give a completely negative genito-urinary history. Our diagnostic routine is to recheck the catheterized bladder urine with special attention directed to the isolation of tubercle bacilli. A flat x-ray plate of the genito-urinary tract is followed by intravenous urography using diodrast. In our experience intravenous pyelography is rarely of aid in detecting an early lesion, but is of decided assistance in the more advanced cases—which constitute a great majority that come under our observation. Cystoscopy with examination of the bladder and split urines for tubercle bacilli and renal function is carried out under caudal anesthesia—we employ 30 cc. of 2 per cent novocain. In a limited number of patients we have employed gas oxygen or spinal anesthesia with 50 mg. of neocaine. Intravenous evipal anesthesia for cystoscopy proved unsatisfactory due to frequent straining and tremors. Bilateral pyelo-ureterograms

are performed on all patients—up to the present time, in over 1500 cases, we have had no fatality or untoward reactions with the use of bilateral simultaneous pyelo-ureterograms. At the present time we employ hippuran for retrograde pyelography.

The coexistence of renal tuberculosis and nephrolithiasis is not common. Some authors consider the occurrence of renal tuberculosis and renal calculi as associated diseases, whereas

Fig. 62.—Bilateral retrograde pyelography. Early case of tuberculosis. Necrosis is limited to upper right calyx. Middle and lower calyces retain normal appearance. Left kidney normal.

others believe that such an association is unlikely. Our interest in this problem was aroused by the scarcity of cases of nephrolithiasis encountered at Sea View Hospital. During the past five years only six cases of renal calculi were brought to our attention. Of these, four were associated with renal tuberculosis. In a total of 1300 routine autopsies only two cases of renal tuberculosis associated with renal calculi were encountered. The incidence of calculi in tuberculous kidneys was placed by Tatnall at 1.4 per cent, by Howald at 1 to 1.4

per cent, by Olsen at 2.7 per cent and by Crenshaw at 1.8 per cent. According to Eisendrath, renal tuberculosis and calculi are associated in about 1.8 per cent. Our percentage of incidence is even lower and varies between 0.9 to 1 per cent.

The diagnosis of renal tuberculosis is made by the recovery of the organism from the segregated urine plus an

Fig. 63.—Right nephrectomized kidney. Case shown in Fig. 62 on section cortical abscess was found adjoining upper calyx.

alteration in the renal architecture as demonstrated by pyelography. The typical lesions are:

1. Cortical necrosis—"moth-eaten appearance" (Figs. 62, 63).
2. Irregular dilatation of the kidney pelvis (Fig. 64).
3. Obliteration of one or more calyces (Fig. 65).
4. Calyceal abscess (Fig. 66).
5. Stricture of the ureter (Fig. 65).

Treatment.—We believe that the patient with a non-destructive lesion should have sanatorium treatment. It is essential that the patient be kept under observation by both

Fig. 64.—Bilateral renal tuberculosis. Occlusion of upper end of ureter on right and tuberculous hydronephrosis with irregular dilatation of the pelvis and calyces on the left.

the medical and urological staffs. By a nondestructive lesion we mean a patient without urinary symptoms or changes in the pyelo-ureterograms. Such cases are referred to the urologist only because tubercle bacilli have been recovered in a routine urine and then recovered again from one kidney at the time of a urological survey. When the pathologist speaks of healed renal tuberculosis, we believe he refers to the above described case that frequently comes under our observation.

Fig. 66—Bilateral retrograde pyelography. Nephrectomy revealed left middle calyceal tuberculous abscess.

It is quite natural to understand why we rarely, if ever, encounter this type of case in private practice. Some observers prefer the term preclinical tuberculosis of the kidney for this nondestructive lesion, which in our opinion either heals or progresses and becomes the true organ, destructive or chronic renal tuberculosis. We believe that all investigators in the entire field of tuberculosis agree that this type of renal path-

ology calls for surgical intervention. But one must not lose sight of the fact that by no surgical measure is it ever possible to remove all tuberculous tissue from the body, and any surgical procedure must be regarded as but one step in the cure of tuberculosis. All cases that present a destructive lesion are nephrectomized, or if the ureter is dilated, a nephro-ureterectomy is performed preferably under spinal anesthesia.

We feel justified with our results in performing a nephrectomy when a destructive lesion is present in one kidney and a nondestructive or very early lesion is present in the other

Fig. 67.—Advanced bilateral renal tuberculosis. Bilateral nephrostomy. (Patient alive two years after operation.)

kidney. Many of the patients on our service present advanced bilateral lesions—most of them are extremely miserable due to a coexisting ureteritis and bladder involvement. Such an individual in almost constant pain with frequency at five-minute intervals during the day and night presents a problem for medical and surgical management. Cystotomy with a permanent suprapubic tube offered no aid in many. Bilateral nephrostomy has been successful in affording relief (Fig. 67).

We have tried the direct application of ultraviolet radiation to the bladder and to the kidney through the cystoscope. The results in our hands have not been encouraging, and, in our opinion more harm than good is done by the latter procedure. All our cases receive general heliotherapy treatments—both pre- and postoperatively. Those who suffer with bladder symptoms postoperatively are usually improved with bladder lavages and general supportive treatment. Many cases of persistent bladder symptoms are due to an empyema of the ureteral stump; that is why we advocate nephro-ureterectomy.

We should like to go on record as answering some of the debatable questions regarding renal tuberculosis:

1. Can a kidney secrete or excrete tubercle bacilli and remain healthy?

It is our firm conviction that the presence of tubercle bacilli in the urine points to a lesion in the kidney.

2. Can a tuberculous lesion in the kidney heal? Yes, providing it is a nondestructive, miliary lesion and does not occur as a terminal hematogenous dissemination from an extensive organ tuberculosis elsewhere in the body. True clinical renal tuberculosis does not heal.

3. In bilateral renal tuberculosis should the more diseased kidney be removed? Yes—if an early lesion exists in the so-called “good kidney.”

4. Is the bladder picture of aid in diagnosis? In advanced cases only—early renal tuberculosis rarely presents bladder involvement.

GENITAL TUBERCULOSIS

The work of various authorities on tuberculosis of the genital tract in the male has by no means given us a clear-cut and well-defined picture of the condition from either the clinical or the pathological point of view.

It is agreed that the infection may reach the genital tract by way of the blood stream, lymphatics or by continuity of tissue. At the present time, there are two schools of thought on the pathogenesis of this condition. Hugh Young, the lead-

ing exponent of the radical school of treatment of genital tuberculosis, asserts that the seat of tuberculous involvement in the genital tract is in the seminal vesicles and that the prostate is involved in most instances. In a series of 342 urogenital cases reported by Young, it was found that the prostate was the single genital organ most frequently involved. Menville, in a survey of a group of cases at the Mayo Clinic also found that the prostate gland was the organ most frequently involved in tuberculosis of the genital tract in the male. Barney, Caulk, Hinman and many others believe that the epididymis is the seat of primary infection in the genital tract, and are of the opinion that the infection is hematogenous in origin. Cunningham in a review of 4250 necropsy records at the Boston City and Long Island Hospitals found 35 cases of tuberculosis of the epididymis in which gross and microscopic examination of the epididymis and gross examination of the prostate and vesicles were recorded. The vesicles were involved in 25 cases and the prostate was tuberculous in 25 cases. There were ten cases in which the epididymis alone was involved and because of this, he believes that the disease is primary in the epididymis. Barney and Hinman believe that if the prostate is involved first, the infection is secondary to renal tuberculosis which so frequently occurs together with genital tuberculosis.

In a survey of 666 autopsies performed on male patients at Sea View Hospital, tuberculosis of the genital tract was found in 67 cases. Genital tuberculosis occurs during the age of greatest sexual activity. In our group, the average age was thirty-nine years, with the ages ranging from two to sixty-seven years. The majority of the cases were white and this is commensurable with the fact that the ratio of white to colored autopsies at our institution is 2.5:1.

Primary tuberculosis of the genital tract is exceedingly rare. Many authorities believe that it does not exist. Koll, in 1915, reported a case of primary tuberculosis of the prostate. The prostate which was removed showed tuberculous involvement on gross and microscopic examination. There was no other evidence of tuberculosis elsewhere in the body.

In a review of the literature up to that time, he found two more cases of primary genital tuberculosis. We have never seen a case of primary tuberculosis of the genital tract. The difficulties attending the discovery of extragenital foci in many cases must always be borne in mind. It is generally believed that genital tuberculosis is secondary to some other focus in the body. This focus is most frequently found in the respiratory tract. Barney in a study of 154 cases of tuberculous epididymitis found tuberculosis of other parts of the body in 55.8 per cent. Involvement of the lungs was most common, 22.7 per cent. Bumpus and Thompson in a study of a series of cases of tuberculous epididymitis found extragenital tuberculosis in 54.8 per cent of cases. In our group of 67 cases there was clinical and roentgenological evidence of active pulmonary tuberculosis in all but five instances. Four of these five cases had bone tuberculosis and all of them had renal tuberculosis. On postmortem examination, pulmonary tuberculosis was found to be present in every case. The pulmonary disease was of the caseous pneumonic type in 77 per cent of the cases. In 3 cases fibrotic (healed) lesions were found. The remaining 12 cases showed nodular or miliary tuberculosis. There were 11 cases of tuberculosis of the spine, bones, and joints; and there were 8 cases of tuberculous meningitis.

It is extremely common to find genital and renal tuberculosis in the same patient, and in others while urinary tuberculosis cannot be proved, it is often suspected. In the diagnosis of genital tuberculosis, evidence of a tuberculous lesion in the urinary tract should be sought for.

Webb Johnson is of the opinion that the infection is carried by the urinary tract in most instances. Menville found renal tuberculosis in 77 per cent of his series of 65 cases of genital tuberculosis in the male. He feels that this justifies the belief that in the majority of cases, involvement of the genital tract is secondary to renal tuberculosis. In Bumpus and Thompson's series of 300 cases, renal tuberculosis was found in 110 cases. In 100 cases of genital tuberculosis, Thomson Walker found accompanying urinary tuberculosis in 37 cases. Camp-

bell believes that the pathogenesis of tuberculosis in the male genital tract with renal tuberculosis is different from that in cases without tuberculosis of the kidneys.

In the opinion of Campbell, genital tuberculosis without involvement of the kidneys is an hematogenous infection and starts in the epididymis, whereas the same with renal involvement reaches the genital tract by way of the urinary passages and the prostate and seminal vesicles are the first to be invaded.

In our series, we divided the cases into the two groups as suggested above. Out of our 67 cases, 51 or 76.1 per cent had renal involvement. The renal type of tuberculosis was subdivided into two groups. The ulcerative type, better known as the organ tuberculosis of the kidney, or the surgical kidney; and the miliary or nonsurgical kidney. Fourteen or 27.5 per cent of cases were of the organ type of renal tuberculosis. Only 3 of these cases were bilateral. The remaining 37 cases were of the nonsurgical or miliary type. Here on the other hand the majority of cases showed bilateral lesions.

It is interesting to know that 10 of the 14 cases of organ tuberculosis in the kidney were diagnosed antemortem by means of intravenous or retrograde pyelography. Although the urine was positive for tubercle bacilli in many instances, this alone could not be taken as an absolute indication of the presence of renal tuberculosis. These patients had tuberculosis of the genital tract and it was impossible to determine from which lesion the bacilli were derived. Another question to be considered is whether or not tubercle bacilli can be excreted in the urine without a definite lesion in the urinary tract. Fullerton and Hillier assert that in advanced pulmonary tuberculosis, bacilli may be excreted through the urinary tract without a tuberculous focus in that tract. It was not until recently that doubt has been thrown upon this concept by Menton, and only a short time ago by Medlar. Greenberger, Wershub and Auerbach surveyed a series of 500 cases at Sea View Hospital two years ago and their conclusions were similar to those derived by Medlar.

In the cases of coexisting renal and genital tuberculosis it

is extremely difficult to determine which lesion occurred primarily. The reason for this is that tuberculosis of the urinary tract may cause little or no symptoms, and so it becomes almost impossible to detect the duration of the disease with any degree of accuracy. The classical symptoms: frequency, nocturia, urgency and dysuria are common findings in tuberculosis of both the urinary and the genital tracts, and consequently cannot be of any great value in determining which one of these tracts is involved. In 2 of our cases there was involvement of an epididymis many years before the onset of either pulmonary or renal symptoms. In 1 case there was a history of gonorrhea and consequently it was impossible to ascertain whether the epididymitis was due to a tuberculous or gonorrheal infection. In the other case an epididymectomy had been performed but here, too, we were unable to find out the etiological factor for removal of the organ. The majority of authorities agree that an ascending infection from the genital to the urinary tract is extremely rare, and many urologists, including ourselves, say that they have never seen it.

In determining the frequency with which the various organs of the genital tract were involved, our survey disclosed some very interesting findings. The prostate gland was involved together with one or more of the other genital organs in 60 out of our 67 cases. Even more important is the fact that the prostate was the sole tuberculous involvement of the genital tract in 21 or 31.5 per cent of the entire group. Menville in his 65 cases found the prostate tuberculous in 86.4 per cent of cases. In no reported series of cases, however, was the prostate alone infected nearly as frequently as we found it to be.

We divided our cases into those with renal involvement and those without tuberculosis of the kidney. In our 16 cases with no gross or microscopic evidence of tuberculosis in the kidney we found the prostate gland involved in 14 or 87.5 per cent of these cases. In the other cases there was tuberculosis of the seminal vesicle in conjunction with other parts of the genital tract. In 3 of this group the prostate was the sole genital

organ involved. Therefore, we find that we cannot agree with Campbell, Barney, Hinman and others that the epididymis is the site most frequently involved in genital tuberculosis even in the absence of renal lesions.

The clinical diagnosis of tuberculosis of the prostate was made in about one third of the cases. If all of our cases had been thoroughly worked up by the urological department, we feel certain that the percentage of clinical diagnoses would have been much greater. The symptoms and findings of this condition are very varied indeed, undefined and not clear. Often the diagnosis can only be made late in the disease.

In our series the following clinical findings were most significant:

1. Enlargement of the prostate.
2. Irregularity and nodulation.
3. Asymmetry between the two lateral lobes.
4. Induration.
5. Boggiess and a fluctuant sensation usually on one side.
6. The prostate was not tender in the great majority of instances. In only 4 cases was tenderness experienced.
7. In 2 cases the prostate was definitely smaller than normal.

The great variation in the physical findings can be explained by the character of the pathology found at postmortem examination. Here again it may be wise to consider the ulcerative, and the nodular and caseous lesions as separate groups. There were 9 cases with definite ulcerations in the prostate. Eleven cases had firm, nodular, fibrotic prostatic lesions and in the remaining 40 cases there were areas of caseation present on gross and microscopic examination. In only 6 cases was one lobe of the gland involved. In 54 the lesions were diffuse and in 2 cases the prostate was almost completely excavated. The clinical and pathological description as to the location and type of tuberculous disease corresponded in 94 per cent of the cases.

The organ which was involved second in order of frequency was the epididymis. Tuberculosis of the epididymis in con-

junction with some other portion of the genital tract occurred in 30 or 44.8 per cent of our cases. It is of extreme importance to note that the epididymis as the sole organ of genital tuberculosis was involved in only 3 cases. In all of these instances there was extensive bilateral disease of the kidneys. In the majority of cases both epididymes were involved. The right epididymis was tuberculous more frequently than the left in the remaining cases.

The diagnosis of tuberculosis of the epididymis is frequently difficult to make. In a large number of patients with genital tuberculosis the only findings are limited to the epididymis, and therefore a careful differential diagnosis of tuberculosis of the epididymis must be considered. Of the conditions that must be ruled out, the most important are:

1. Lesions due to trauma.
2. Lesions of infectious origin:
 - (a) Gonorrhea with hydrocele.
 - (b) Lues of testes and epididymes.
3. Tumors of the epididymes:
 - (a) Angioma.
 - (b) Lipoma.
 - (c) Fibroma.
 - (d) Carcinoma.
 - (e) Dermoid.
4. Tumors of the spermatic cord:
 - (a) Lipoma.
 - (b) Fibroma.
 - (c) Sarcoma.
 - (d) Hematocele.
 - (e) Spermatocele.
5. Tumors of the testicular tunics:
 - (a) Sarcoma.
 - (b) Fibroma.

Before making the diagnosis of tuberculous epididymitis in any acute lesion in the epididymes, certain other factors should be considered. The discovery of an extragenital tuberculous focus often makes the diagnosis certain.

In the majority of instances, the site of tuberculous infection in the epididymis is in the globus minor. Tuberculous epididymitis may start as an acute swelling with pain and en-

largement. There may be a hydrocele formed in some instances. This may mask the underlying pathology. In most instances there is enlargement of a portion of the epididymis. This is hard, irregular or nodular and only rarely painful or tender. In many cases focal suppuration or fluctuation may be recognized. The swelling of the epididymis is painful in about 50 per cent of cases. There may be draining scrotal sinuses which are extremely hard to close. In our series, scrotal sinuses were found in only two instances. The swelling of the testicle with or without tenderness, the presence of an enlarged thickened, nodular, indurated epididymis with or without draining sinuses, and a thickened and beaded vas were of greatest aid in making the diagnosis of tuberculosis of the epididymis. The important fact still remains that the discovery of a tuberculous lesion elsewhere was of greatest aid in making the diagnosis of tuberculous epididymitis.

The seminal vesicles were involved in 29 of our 67 cases, and were the only demonstrable tuberculous foci in the genital tract in three instances. Here as with the epididymis the involvement was bilateral in a great majority of cases. In the remaining cases the right seminal vesicle was involved much more frequently than the left. It will be recalled that the same condition was found to be true in tuberculous epididymitis.

The clinical diagnosis of tuberculous seminal vesiculitis is often difficult to make. Cunningham found that in many of his cases of tuberculous epididymitis, the lesions in the prostate and vesicles were not and could not be detected by rectal palpation.

With the available clinical material at our disposal, the diagnosis of tuberculous seminal vesiculitis was made in seven instances. The diagnostic features were thickening, induration, distention and enlargement. Vesiculograms were attempted in a few cases but failed to yield definite results. It was extremely difficult to visualize the vesicles.

The majority of authorities are of the opinion that tuberculous infection of the testis is always secondary to tuberculosis of the epididymis. Tuberculosis starting in the testis is ex-

tremely rare. The testis was infected in 15 cases of our group, but there was not a single instance where the genital involvement was present in the testis only. Both testes were involved in 8 cases, the right in 4 and the left in 3 cases. In most instances the disease was not extensive enough to be detected on physical examination. When signs were present the most prominent ones were irregularity, induration and adhesion.

The cases of multiple involvement of the genital organs were then investigated and several important facts were brought to light that are more graphically detailed in Tables 1 to 5.

A detailed examination of the various ways in which the genital tract was involved revealed that in unilateral lesions of the seminal vesicles, epididymes and testes, there was no evidence of cross infection. In other words, we found no cases in which, for example, the right seminal vesicle and the left epididymis were involved. Our findings agree with the contentions of others that cross infection in the genital tract is rare, and that in most instances involvement of the kidney and various organs in the genital tract occur on the same side.

The effect of gonorrheal infection on tuberculosis of the genital tract deserves some mention. Donges among others believes that nontuberculous infections of a genito-urinary tract may, in the presence of pulmonary tuberculosis, predispose to tuberculous involvement of the genito-urinary tract. The nontuberculous infection serves as a locus minoris resistentiae and as a result, tubercle bacilli accumulate there. Sixteen of our cases gave a clinical history of gonorrheal infection. All of these cases, except 1, had extensive pulmonary tuberculosis, and in all but 2 cases there was extensive renal tuberculosis. One case had tuberculosis of the vertebrae. In spite of the severe extragenital tuberculous involvement, 5 of these cases showed the prostate to be the only genital organ involved. In 1 case, only the right epididymis was infected while the remaining cases revealed extensive genital involvement. Thus there was no reason to believe that in our group

the preexisting gonorrheal infection served as a predisposing factor in the invasion of the genital tract by the tubercle bacillus.

We believe that a few words concerning therapy will not be amiss. It was maintained previously that there are two distinct schools of thought with reference to this condition. The exponents of radical surgery, led by Hugh Young, believe that excision of the entire genital tract is the treatment of choice. The reason for this treatment is the belief that the disease arises in the genital tract in the prostate and vesicles, and that from these foci the bacilli may involve any other portion of the tract. The radical operation has, however, introduced an immediate postoperative mortality which in the experienced hands of Young, himself, reached 4 per cent in one of his series.

The advocates of more conservative therapy, namely, Barney, Hinman and others, believe that the epididymis is the primary seat of infection in the genital tract. They therefore recommend epididymectomy with ligation of the vas high up on the affected side, and a prophylactic ligation with removal of a small portion of the vas on the opposite side. They maintain that a large number of persons are rendered sterile by genital tuberculous involvement so that ligation of the opposite side should be done without hesitation. Even in the face of involvement of the prostate and seminal vesicles the conservative school, to which we subscribe, continues to recommend epididymectomies and removal of infected portions of the testis leaving apparently healthy testicular tissue behind. After epididymectomy the prostatic lesions often tend to retrogress and become cicatrized. Supportive measures including heliotherapy, tuberculin and small doses of x-ray have been advocated by some. We prefer heliotherapy and rest as supportive treatment.

The prognosis of genital tuberculosis in the male is not very good regardless of the type of surgery employed. The course following operative interference depends to a large ex-

tent on the nature of the tuberculous process or processes elsewhere in the body. Several cases have been reported in which a rapid generalized miliary tuberculosis with terminal tuberculous meningitis developed shortly after operative interference. We have never noted such a course following surgery.

The rate of recurrence after surgical procedure is about 40 per cent. In Bruns' series of 111 cases there was recurrence in 60 per cent of the unilateral cases from three to thirty-four years after operation. Barney in 49 cases of unilateral lesions observed recurrence on the opposite side of 37 per cent of cases within three years following epididymectomy and orchidectomy. Bumpus and Thompson found a recurrence of 39 per cent in the opposite side within one year after operation.

SUMMARY AND CONCLUSIONS

RENAL TUBERCULOSIS

1. Renal tuberculosis is blood-borne.
2. Renal tuberculosis is usually associated with pulmonary tuberculosis—it is never primary.
3. The nondestructive, closed or miliary renal lesion is common and is bilateral in more than 80 per cent.
4. The destructive, open, organ, or chronic surgical tuberculosis of the kidney is usually unilateral—is notably deficient in symptoms which are explained by the absence of involvement of the ureter and bladder.
5. The diagnosis of renal tuberculosis rests on the recovery of the tubercle bacilli, plus alterations in the renal architecture as demonstrated by retrograde pyelography.
6. The presence of tubercle bacilli in the urine means that a lesion exists.
7. Treatment of the clinical, organ, open or destructive renal lesion, is always surgical.
8. The miliary, closed or nondestructive renal lesion should be treated medically—this type lesion may heal, but calls for close cooperation and observation by the urologist and internist.

9. The coexistence of renal tuberculosis and nephrolithiasis varies between 0.9 and 1 per cent in our series.

GENITAL TUBERCULOSIS

10. Tuberculosis of the genital tract was found in 67 or 10.1 per cent of our series of male autopsies. This figure compares favorably with those reported by other investigators.

11. The average age for the group is 39.8 years. This figure is a little higher than those reported by most authorities.

12. There was extragenital tuberculous disease found in every case.

13. Renal tuberculosis was present in 76.1 per cent of the cases.

14. The prostate gland was the single genital organ most frequently involved. From the standpoint of frequency the epididymis, seminal vesicles and testicles were infected in the order named.

15. Tuberculosis of the prostate gland as the sole involvement of the genital tract was present in 31.5 per cent.

16. The symptoms and diagnostic features of tuberculosis of the various genital organs were reviewed and a comparison of the clinical and pathological findings was made. In some cases the clinical data were not sufficient for the proper diagnosis.

17. Our findings agree with those of Bumpus and Thompson that in most instances involvement of the kidney and various organs in the genital tract occurs on the same side and that cross infection is rare.

18. The effects of a preexisting gonorrheal infection on tuberculosis of the genital tract were studied. Although most of our cases showed extensive bilateral involvement, our results were such that we could not find any relationship of the gonorrheal to the tuberculous infection.

19. The observation of other investigators that more than 30 per cent of the victims of genito-urinary tuberculosis succumb to miliary tuberculosis and tuberculous meningitis was not encountered in our series.

20. We believe the treatment of genital tuberculosis should be conservative. We do not subscribe to the radical surgical removal of the genital tract.

CLINIC OF DR. M. KOVNAT

SEA VIEW HOSPITAL

PREGNANCY AND TUBERCULOSIS

IN 1935 Ornstein and the author¹ reviewed the course of 85 pregnant women suffering with tuberculous pulmonary disease. The study was prompted by the lack of any guiding indications in the management of this complication and the apparent undercurrent of pessimism in its outcome. This pessimistic attitude dates back to Ortega² with short periods when the prognosis veered to the opposite extreme. In general, the reports from early investigators indicate a deleterious effect on the disease in 33 to per cent of the cases. Kaminer³ reports bad results in 50 per cent of his cases, Merletti⁴ 50 per cent, Lempert⁵ 75 per cent, Von Rosthorn⁶ 75 per cent, Von Bardeleben⁷ 71 per cent, Reiche⁸ 77 per cent, Parry⁹ 50 per cent and Bacon¹ reports 33 per cent of deaths in the first year.

As the data of our cases were being collected, it appeared as though the prevailing pessimistic outlook in such cases was justified, but when the facts were entirely assembled and analyzed, a different aspect presented itself. The 85 cases studied at Sea View Hospital had an average stay in the institution before confinement of two and one-tenth months and after delivery, of three months. Of the 85 cases 31 or 36 per cent died, 15 or 18 per cent were unimproved or showed progression of their pulmonary disease and 39 or 40 per cent were improved. At first glance these figures which show 54 per cent of the cases progressed or died appeared to follow the results of the other investigators and revealed a generally poor

prognosis for this complication. When these figures, however, were compared with a large group of females from the same institution, uncomplicated by pregnancy, the results of the pregnant group did not show up unfavorably. In the nonpregnant group of 5470 admissions, 1850 or 33 per cent died, 1696 or 31 per cent were unimproved and 1969 or 36 per cent improved. In this group of nonpregnant females, therefore, 64 per cent died or had a progression of their disease. These two groups were comparable in practically every respect, sources of admission into the institution, their age, the extent and character of the pulmonary pathology and the management employed in their treatment.

The analysis of the final outcome in the 85 pregnant cases yielded no clue as to how the individual patient would be affected by the complication, until each case was studied individually in respect to the character of its own pulmonary pathology. The qualitative classification devised by Ornstein, Ulmar and Dittler¹¹ was employed. In this classification the tuberculous pulmonary pathology is grouped into three divisions: the resolving exudative and exudative productive form; the chronic productive form, and the malignant caseous-pneumonic form of the disease. The following case reports illustrate this classification and the course of the disease in each group.

The Resolving Exudative Form.—S. R., age twenty-one, gravida 1, was admitted to the institution December 3, 1932, with a history of loss of weight, slight cough and fatigue and a six weeks' pregnancy. Physical examination revealed a white female, poorly nourished, but not appearing acutely ill. Over the right anterior chest, there was dullness, bronchovesicular breathing and many moist râles. The sputum was negative. The x-ray, taken on December 5, 1932, revealed a homogeneous density over the right upper lobe and a similar but less extensive shadow in the left infraclavicular region. With routine rest treatment, the cough subsided and the physical signs diminished. On August 26, 1933, the patient had a normal, spontaneous delivery. An x-ray taken on September 21, 1933, revealed resolution of the exudative process. On September 28, 1933, she was discharged as an arrested case, free of all symptoms. In retrospect, this patient went through an uneventful pregnancy, confinement and puerperium while taking a successful rest cure for her exudative productive pulmonary tuberculosis.

This case illustrates the resolving exudative form of the disease. It is an acute process and the lesions vary from a lobule to an entire lobe. The reaction is chiefly serous with some fibrin and cellular elements. There is little or no destruction of tissue. Resolution may therefore occur without leaving a trace or with a few fibrotic strands as evidence of previous infection. In the benign exudative group where the dose of bacilli is small and the tissue sensitivity high, resolution may occur in from six weeks to six months. In the exudative-productive form, because of some fibrin and cellular deposits, resolution takes a longer time. The prognosis is uniformly good in this form of the disease particularly with proper rest treatment.

There were 9 such cases in our study. There were no deaths in this group; 7 were discharged from the hospital improved, 2 were discharged as unimproved. In a later follow-up of these cases, 6 were traced. None of these had died nor was there any evidence of reactivation of the disease.

The Chronic Productive Form.—L. E., age twenty-three, gravida II, was admitted to the institution on April 12, 1933, with a history of cough and hemoptysis dating back to one year previously and a pregnancy of four months' duration. Physical examination revealed a white adult female, appearing fairly well nourished and not acutely ill. The physical signs in the chest were scanty, occasional fine râles elicited over the right upper lobe. Subjectively, the patient had few symptoms. The sputum on admission was positive, Gaffky 3. The x-ray on April 12, 1933, revealed proliferative changes in the right infraclavicular region. Her course while in the hospital, was entirely uneventful except for continued gain in weight and a return of negative sputum from June until her discharge in October. On September 6, 1933, she had a normal spontaneous delivery. An x-ray on September 26, 1933, revealed the same proliferative changes in the right infraclavicular region with apparently no change from the time of her admission. On September 28, 1933, she was discharged as apparently arrested. In retrospect this case likewise went through a normal pregnancy, confinement and puerperium with no effect on her pulmonary disease other than the usual improvement noted with routine rest care in this form of pathology.

This case illustrates the chronic productive type. The reaction of this form is chiefly cellular and acinous in distribution. The process usually begins in the apex, and slowly

spreads through the lungs. There are few symptoms of toxemia. The prognosis likewise is usually good in this form of tuberculosis. This form of pathology usually occurs where tissue sensitivity is low and dosage of tubercle bacilli is small. There were 25 cases of this type. No deaths occurred during their stay in the hospital. Twenty-three were discharged as improved and 2 as unimproved. In a later follow-up study, 14 of these cases were traced. Two of these had further slow progression of their disease as sometimes occurs in this form and ultimately died. Their deaths both occurred about one year after the delivery. One of these had been originally discharged as unimproved. The remaining 10 cases have apparently had no reactivation of their lesion and are still considered as arrested cases.

The Caseous-pneumonic Form.—G. B., age twenty-four, gravida III, was admitted to Sea View April 4, 1933, with a history of pulmonary symptoms dating back six months previously. Physical examination revealed a poorly nourished adult white female with extensive physical signs through the right lung. The sputum was negative on admission. An x-ray taken on April 5, 1933, revealed a caseous-pneumonic lesion involving the right upper lobe with a marginal pneumothorax which was initiated at the previous institution a short time before. The patient, however, refused to cooperate and resisted further refills. The sputum soon after turned positive. On July 7, 1933, she went through a spontaneous normal delivery. Clinically her condition continued to go downhill. An x-ray on September 25th, revealed further extension of the pathology in both lung fields. The patient's condition continued to grow worse and she died on November 15, 1933.

In reviewing this case we note a rapid progression of the disease, ending in the death of the patient four months after confinement. In this form of tuberculous disease there is high tissue sensitivity and large dosage of bacilli. The reaction is severe, with resultant death of tissue. There is both caseation and necrosis. Following liquefaction of the whole mass the dead tissue is sloughed out, resulting in cavity formation, the chief characteristic of this form of the disease. The prognosis in this form is uniformly bad, and improves only as it lends itself to closure of the cavity. In the case cited above the

patient gave up her only opportunity for recovery when she refused to continue her pneumothorax.

Our original study contained 51 cases of this form of the disease. Thirty-one died, 10 were discharged as unimproved and 10 were discharged as improved. In a later follow-up of the 20 discharged cases, 6 had died. In order to determine whether the pregnancy was responsible for the unusually high mortality, a group of 51 nonpregnant females suffering with the similar caseous-pneumonic form of the disease was studied. In this group there were 23 deaths, 25 showed progression of their disease, and only 3 were improved. The only apparent difference was the speed with which the condition progressed. In the pregnant group the average duration of life was two and one-tenth months. In the nonpregnant group it was ten and three-tenths months.

From the impressions gained as a result of this study a working formula was laid down to guide the staff in the management of this complication in the individual case. In brief, it advised the attending physician to expect no deleterious effect in the exudative-productive and chronic productive forms of the disease. In the caseous-pneumonic forms, active therapeutic measures for closure of cavities, so essential in all such cases, was all the more imperative in the pregnant females, if an early exitus was to be avoided.

We have had an opportunity to test this formula in 59 cases admitted to Sea View subsequent to the original study above cited. Thirty-five were of the caseous-pneumonic form, 14 the exudative productive, and 10 chronic productive. Fifteen died on the average of two months after the delivery. They all belonged to the caseous-pneumonic group. Fifteen were unimproved or progressed. These were all likewise from the latter group of 35. There remain 5 of 35 caseous-pneumonics that did not show progression of their disease. One had her disease arrested by means of thoracoplasty subsequent to her confinement. Another was a pneumothorax case with a good collapse of the diseased process. Another had an initial collapse instituted two months prior to her delivery

and continued after her discharge. A fourth had a thoracoplasty before her pregnancy.

Of the remaining 14 exudative-productive and 10 chronic productive cases none died nor showed any aggravation of their condition after their delivery and puerperium. They were discharged on the average six months after their confinement.

We are now doubly convinced, both from our original study, and the subsequent observations, that the proper qualitative diagnosis and classification of the type of pulmonary pathology will determine the course of the disease when complicated by a pregnancy. We reiterate, the exudative-productive and chronic productive forms have the usual favorable prognosis, regardless whether we are dealing with or without this complication. In the caseous-pneumonic form the appearance of a pregnancy is only another indication for hastening all active measures to close the cavity. If this can be accomplished the complication will not interfere with the patient's improvement and an ultimate arrest of the disease. If it cannot, the usual progression of the disease in this form will be hastened and an early exitus a frequent occurrence.

I wish to thank Dr. H. Katzev for aid in compiling the data.

CLINIC OF DR. ISRAEL G. EPSTEIN

SEA VIEW HOSPITAL

FLUOROSCOPY AND x-RAY IN PNEUMOTHORAX THERAPY

RIGHTFULLY, collapse therapy is at present the greatest weapon at our disposal in the treatment of the caseous-pneumonic form of pulmonary tuberculosis. Of the collapse procedures, the pneumothorax while simple as to technic and attended with comparatively slight risk and morbidity, has been called upon more and more of late in the attempt to control the tuberculous cavity.

Physical examination although very valuable and informative, has its limitations. The percussion note with its extent of hyperresonance does not give the examiner a true picture as to the extent of lung collapse. The diminution of breath sounds may be deceiving particularly when there is a column of air completely surrounding a partially collapsed lung with a patent cavity. The coin sound, when obtained correctly, may map the edge of the collapsed lung. However, when one uses this procedure on a number of cases, he soon realizes the shortcomings of this test.

The fluoroscopy and x-ray examination is an invaluable aid in the course of pneumothorax therapy for here we have a visual picture of the lung that is undergoing collapse treatment. For the sake of clarity, the course of pneumothorax therapy may be divided into four periods. The first, before collapse therapy is instituted; the second, the primary pneumothorax with its initial reëfills; the third, the pneumothorax maintenance; the fourth, the period of reexpansion of the collapsed lung. If these four periods are carefully controlled roentgen-

ologically, a more intelligent, safe, and comfortable pneumothorax is likely.

THE PERIOD BEFORE COLLAPSE THERAPY IS INSTITUTED

Physical findings when positive are important in the recognition of the caseous-pneumonic form of pulmonary tuberculosis. The deep-seated cavity or the one with a good deal of compensatory emphysema may give no or scant physical findings. Frequently a large solitary cavity can be seen over which area no altered breathing or râles are heard. The localization of the pathology is important and a record should be kept by means of an x-ray film. Throughout the entire course of treatment an attempt will be made to keep the pathological portion well collapsed with less attention paid to the part of the lung free of cavitation. A record, by means of the x-ray, is kept of the condition of the lung prior to the institution of collapse therapy. This is compared with the picture of the re-expanding lung when the time is thought to be propitious for lung reexpansion. Stereoscopic x-rays, anteroposterior, postero-anterior, lateral views of the chest as well as fluoroscopy are used in determining the extent, character and position of the pathology in the involved lung.

THE PRIMARY PNEUMOTHORAX

A primary pneumothorax is done with the initial refills. After the first few treatments, a visual picture is necessary to determine the location of the instilled air and the lung edge. The collapse of healthy lung tissue with no effect on the diseased lung tissue is undesirable. A successful pneumothorax is one that compresses the pathological portion of the lung. At this time, the character of the collapse is noted and the decision whether to continue pneumothorax treatments is made.

THE PERIOD OF PNEUMOTHORAX MAINTENANCE

A visual appraisal of the extent of collapse is obtained before and after each pneumothorax inflation. From this information, one could estimate the amount of air necessary to

control the diseased portion of the lung. From the extent of collapse before a refill, one can infer the amount of air absorbed from the last treatment to the present one when one keeps in mind the fluoroscopy picture of the position of the collapsed lung after the last inflation. In this way one may most accurately judge the amount of air necessary at each treatment and the interval of time between inflations.

If the lung is free, the excavated portion of the lung may collapse to a greater extent than the uninvolved portion. This may be due to the loss of tissue in the caseous-pneumonic lung with poor aeration and partial atelectasis (Ornstein) or to the atelectasis caused by a more complete stenosis of the bronchus to the lobe as a result of the shifting of the lung by the pneumothorax (Coryllos). When this selective collapse of the involved portion of the lung is observed under fluoroscopy, one could easily keep the uninvolved portion reexpanded to a great extent by varying the amount of air given at each refill. In this way, a control of the tuberculous lesion is obtained while the healthy portion retains its function. This is more important when bilateral collapse therapy is attempted. Here the vital capacity is low and the margin between comfort and discomfort is narrow. A conservation of normal lung tissue is important, obtained only by careful roentgenological control. No bilateral pneumothorax therapy should be attempted without the facilities of repeated roentgenological examinations.

The comfort of the patient must be considered during pneumothorax treatment. A mediastinum pushed over to the contralateral hemithorax does not exert sufficient pressure on the pathology. A fixed mediastinum against which the pathological lung may be pushed is to be sought. An accurate appraisal of the flexibility of the mediastinum can be obtained only on a careful fluoroscopy when changes of position of the mediastinum could be observed on inspiration and expiration. The maximum shift is noted in the anteroposterior position upon expiration. In the expiratory phase, in the presence of a mobile mediastinum, the heart and mediastinal contents shift

markedly to the contralateral side. Constant fluoroscopy and x-ray examinations before and after pneumothorax refills are necessary to keep the mediastinum in the midline to promote fixation in that position. A good deal of the dyspnea of which pneumothorax patients complain may be traced to a mobile mediastinum with too great a shift of the heart and mediastinal contents to the contralateral thorax.

Fig. 68.

It is generally admitted today that in only 40 out of 100 cases in which pneumothorax is attempted, is satisfactory collapse of the lung obtained. In 10 per cent, the pleural cavity is found completely obliterated and in 50 per cent adhesions are present preventing closure of cavities (Coryllos). These bandlike formations, attached to the visceral and parietal pleura are often sufficient to prevent the pathological portion of a lung from collapsing. The adhesions are not always visible in the orthodox x-ray positions. An x-ray of the chest in the expiratory phase is an aid in bringing out the extent and char-

acter of the adhesive bands. In this position, the maximum lung collapse could be visualized rendering the adhesions more taut. We have found x-rays of the chest taken in lordotic position of great aid in determining the extent, thickness, direction and attachments of adhesive bands. With these x-rays, one can determine to a great degree the advisability of attempting to sever these pleural bands.

Fig. 69.

Figure 68 is an x-ray demonstrating a pneumothorax of the left chest with the pathology not collapsed completely. A cavity is still seen patent in the midportion of the uncollapsed lung. Suggestion of adhesions is seen but none can be traced clearly.

In the lordotic position, four distinct adhesion bands can be traced as indicated in Fig. 69. These were confirmed on thoracoscopy when the surgeon's drawing almost completely coincided with the x-ray picture.

Figure 70 is an x-ray taken ten weeks later. Dr. P. N. Coryllos has severed all the adhesions seen on the lordotic

x-ray. The pneumothorax was then more effective in securing a complete collapse. The cavity seen in the first figure could not be visualized.

The technic of lordotic x-rays is simple. A preliminary fluoroscopy is done, the best visualization of the adhesion bands is sought by placing the patient in the anteroposterior and postero-anterior lordotic position. The curve of the body is noticed and then reproduced in taking the x-ray. The x-ray

Fig 70

tube is placed high and angulated to cause sufficient distortion to bring out more clearly the adhesion bands.

Roentgenograms of the thorax in the lateral and oblique positions are useful in determining the extent of an irregular collapse. When one gets into difficulty with an irregular collapse or a reexpanding lung, fluoroscopy in the oblique positions marking the near point over the pneumothorax pocket, enables one to obtain the point at which the pneumothorax

needle should be inserted. In this way a reexpanding pneumothorax may be maintained and vascular accidents avoided.

In the presence of fluid, a visualization of the collapsed lung is comparatively difficult. x-Ray pictures may be taken with the patient lying on the uninvolved side thus allowing the fluid to gravitate toward that side and the midline of the body. The edge of the collapsed lung is therefore exposed and a

Fig. 71.

proper visualization of the lung edge obtained. A film with the patient lying on the involved side may also aid in visualizing the extent of lung collapse under accumulated fluid.

Figure 71 is an x-ray of a patient who developed fluid in the right thorax during the course of pneumothorax therapy. The edge of the collapsed lung could not be clearly traced. Therefore the extent of lung collapse could not be accurately observed.

Figure 72 is an x -ray of the thorax of the patient shown in Fig. 71 taken in the anteroposterior position. She is lying on her right side. The fluid gravitated downward exposing the collapsed lung. The entire lung edge could be traced with ease.

A proper fluoroscopic and x -ray control is very necessary during the course of pneumothorax therapy. By this visual

Fig. 72.

check, one is able to judge the efficacy of the treatment, the amount of air to be given at each inflation, the interval between treatments, and the control of both adhesions and complicating fluid.

THE PERIOD OF REEXPANSION OF THE COLLAPSED LUNG

After a sufficient period of pneumothorax therapy, the lung is allowed to reexpand. Repeated fluoroscopic and x -ray examinations reveal no open lesions in the collapsed lung, the sputum examinations demonstrate no tubercle bacilli. The lung is allowed to slowly reexpand under frequent roentgenological examinations. If the lesion in the involved lung seen

prior to pneumothorax therapy is completely healed, the lung is allowed to approach the thoracic wall and become adherent. Shadows seen in the reexpanding lung are compared with corresponding areas in the involved portion prior to treatment. Small effusions, folds in the pleura and scar tissue may be confusing. A close check is necessary to reassure the physician that no open lesion exists.

An atelectatic lung may not reexpand fully so that the mediastinum is drawn over to the same side as the air is absorbed. This in turn causes an emphysema of the other lung in an effort to fill the enlarging hemithorax. Under fluoroscopy and x-ray this is observed and steps taken to correct this condition.

SUMMARY

The importance of fluoroscopy and x-ray in pneumothorax therapy is discussed. Frequent roentgenological control is important in every stage of pneumothorax therapy. At times, x-ray and fluoroscopy in different positions are necessary to keep the lung and pneumothorax in view. x-Rays taken in the lordotic position help in the visualization of adhesions preventing good lung collapse.

CLINIC OF DR. S. EDWARD KING

FROM THE METABOLIC SERVICE, SEA VIEW HOSPITAL AND MEDICAL SERVICE, NEW YORK POSTGRADUATE HOSPITAL

THE TREATMENT OF DIABETES COMPLICATED BY TUBERCULOSIS

Introduction.—The coexistence of diabetes and tuberculosis in the same patient introduces special problems which do not exist in either disease alone.

Tuberculosis tends to develop in diabetics who have neglected their condition for long periods. Most patients are of fairly advanced age, necessarily so, since the incidence of diabetes is low under forty.¹ In Root's² series of 245 tubercular diabetics, about 50 per cent were over fifty years of age. Similarly about 75 per cent of our cases were forty-five years or older. Such individuals are very liable to suffer from the sequelae of uncontrolled diabetes, namely, vascular sclerosis and coronary disease. These are important complications which markedly affect the treatment and prognosis of tubercular diabetics. Possibly they also influence the pathology of the pulmonary infection and its symptoms.

It is the general rule for this group to present mild forms of diabetes. Severe cases are comparatively rare and are confined to the younger age groups and to those with endocrine disorders. Only 15 per cent of our cases could be classified as severe diabetics, and of these more than half were thirty years of age or younger. The frequent history of antecedent coma is not necessarily an index of severity, but rather of inadequate or total lack of control of the diabetes.

The pulmonary condition in the majority of tubercular diabetics is usually first recognized at an advanced stage of

the disease. This is true not only in municipal hospitals and clinics, but also in private practice. This situation in itself materially influences the ultimate prognosis of these cases.

It is difficult to account for this unfortunate situation. Most authorities do not believe that pulmonary tuberculosis in diabetics differs materially in its course or clinical signs from that in other patients. If this is so, the explanation is attributable to indifferent diagnosis and failure of those treating diabetes to appreciate the relative frequency of this complication.

Malnutrition is frequently present at the time of hospital admission, particularly in the poorer economic groups in whom diagnosis and treatment of both diseases are delayed. Anorexia, vomiting and laryngeal involvement may interfere with food ingestion and treatment.

Indications and Objectives of Diabetic Treatment.—The immediate indication is to control the diabetes as quickly as possible, while insuring adequate nutrition and weight increase to the estimated normal. The diabetic control must be constant, for even short periods of glycosuria are detrimental to the pulmonary disease.

The general objectives are in no way different from those in ordinary cases of diabetes; namely:

1. Elimination of ketosis and acidosis.
2. Elimination of glycosuria.
3. Treatment of dehydration.
4. Readjustment of body weight and nutrition.
5. Estimation of permanent carbohydrate tolerance and corresponding adjustment of insulin and diet (stabilization).
6. Control of blood sugar, cholesterol, chlorides, etc. (when possible).

Methods.—(A) Diet.

1. *Calories.*—Total calories are calculated from the normal weight and present nutritional status. The appetite, degree of physical activity, presence of fever or toxemia, influence caloric requirements considerably. Even under similar con-

ditions, individuals differ vastly, in their caloric requirements. The total caloric intake must be so adjusted as to permit gain in weight and improvement in nutrition when necessary, the goal being an approximately normal body weight. There is no particular virtue in increasing the body weight much above normal, since obesity has no influence upon the pulmonary disease, but has a distinctly undesirable effect upon the diabetes. Depending upon individual indications, from 1800 to 2500 calories are usually prescribed.

2. *Carbohydrates*. — Moderately high carbohydrate diets^{3, 4, 5, 6} are now generally employed in the treatment of diabetes. Such diets prove more palatable, and within limitations probably stimulate carbohydrate tolerance. They are also of value in preventing hypoglycemia in cases taking insulin. Nor is much more insulin required than with the former high fat diets.^{3, 5}

McCann⁷ has objected to high carbohydrate diets in pulmonary tuberculosis upon the theoretical assumption that the greater CO₂ formation and increased pulmonary ventilation, aggravates the pulmonary pathology. No clinical evidence to confirm this hypothesis has been observed.

3. *Protein*. — It is our practice to employ a fairly, but not excessively high, protein quota; about 90 Gm. daily. There are theoretical objections to the use of high protein diets, adverse effects upon carbohydrate tolerance being reported.^{1, 8, 9} However, the amounts here employed are not sufficiently high to produce any objectionable effect.

There are many reasons why an adequate protein diet must be prescribed in severe cases of tuberculosis. As previously shown,^{7, 10} protein requirements in tuberculosis are greater than normal. This is due to fever, toxemia, increased nitrogen destruction, as well as loss of protein through various channels. Unless this negative balance is prevented, anemia, cachexia, and edema are prone to develop.

4. *Fat*. — High fat diets are undesirable from many points of view. Fatty foods prove unpalatable to individuals confined to bed and suffering from poor appetite. Fats delay

the disease. This is true not only in municipal hospitals and clinics, but also in private practice. This situation in itself materially influences the ultimate prognosis of these cases.

It is difficult to account for this unfortunate situation. Most authorities do not believe that pulmonary tuberculosis in diabetics differs materially in its course or clinical signs from that in other patients. If this is so, the explanation is attributable to indifferent diagnosis and failure of those treating diabetes to appreciate the relative frequency of this complication.

Malnutrition is frequently present at the time of hospital admission, particularly in the poorer economic groups in whom diagnosis and treatment of both diseases are delayed. Anorexia, vomiting and laryngeal involvement may interfere with food ingestion and treatment.

Indications and Objectives of Diabetic Treatment.—The immediate indication is to control the diabetes as quickly as possible, while insuring adequate nutrition and weight increase to the estimated normal. The diabetic control must be constant, for even short periods of glycosuria are detrimental to the pulmonary disease.

The general objectives are in no way different from those in ordinary cases of diabetes; namely:

1. Elimination of ketosis and acidosis.
2. Elimination of glycosuria.
3. Treatment of dehydration.
4. Readjustment of body weight and nutrition.
5. Estimation of permanent carbohydrate tolerance and corresponding adjustment of insulin and diet (stabilization).
6. Control of blood sugar, cholesterol, chlorides, etc. (when possible).

Methods.—(A) Diet.

1. *Calories.*—Total calories are calculated from the normal weight and present nutritional status. The appetite, degree of physical activity, presence of fever or toxemia, influence caloric requirements considerably. Even under similar con-

ditions, individuals differ vastly, in their caloric requirements. The total caloric intake must be so adjusted as to permit gain in weight and improvement in nutrition when necessary, the goal being an approximately normal body weight. There is no particular virtue in increasing the body weight much above normal, since obesity has no influence upon the pulmonary disease, but has a distinctly undesirable effect upon the diabetes. Depending upon individual indications, from 1800 to 2500 calories are usually prescribed.

2. *Carbohydrates.* — Moderately high carbohydrate diets^{3, 4, 5, 6} are now generally employed in the treatment of diabetes. Such diets prove more palatable, and within limitations probably stimulate carbohydrate tolerance. They are also of value in preventing hypoglycemia in cases taking insulin. Nor is much more insulin required than with the former high fat diets.^{3, 5}

McCann⁷ has objected to high carbohydrate diets in pulmonary tuberculosis upon the theoretical assumption that the greater CO₂ formation and increased pulmonary ventilation, aggravates the pulmonary pathology. No clinical evidence to confirm this hypothesis has been observed.

3. *Protein.* — It is our practice to employ a fairly, but not excessively high, protein quota; about 90 Gm. daily. There are theoretical objections to the use of high protein diets, adverse effects upon carbohydrate tolerance being reported.^{1, 8, 9} However, the amounts here employed are not sufficiently high to produce any objectionable effect.

There are many reasons why an adequate protein diet must be prescribed in severe cases of tuberculosis. As previously shown,^{7, 10} protein requirements in tuberculosis are greater than normal. This is due to fever, toxemia, increased nitrogen destruction, as well as loss of protein through various channels. Unless this negative balance is prevented, anemia, cachexia, and edema are prone to develop.

4. *Fat.* — High fat diets are undesirable from many points of view. Fatty foods prove unpalatable to individuals confined to bed and suffering from poor appetite. Fats delay

gastric evacuation and may produce indigestion and vomiting. High fat diets appear to definitely diminish sugar tolerance.¹

For these reasons, the older high fat diets are now rarely used. Sufficient fats are prescribed to bring the diet up to caloric requirements.

5. *Accessory Substances and Minerals.*—Adequate amounts of the accessory food substances are provided by the inclusion of fresh fruit juice, cereal, butter, milk, fruits and green vegetables in the diet daily. In our experience, vitamin B furnished as yeast or in various proprietary products, often exerts a stimulating effect upon appetite and promotes gain in weight.

Adequate calcium, phosphorus, and iron is obtained by the inclusion of milk and fresh vegetables in the daily menu.

6. *Food Distribution.*—Carbohydrates are usually distributed in about equal proportion among the three meals with the noon meal slightly lower in carbohydrate, but higher in protein and fat. When supper is eaten early, as is customary in institutions, it is advisable to serve one glass of milk at night to tide over the long fast, or if preferred, a fruit or dessert. A small amount of carbohydrate is also frequently prescribed in the forenoon. This procedure seems to be of value in preventing excessive fluctuations in blood sugar, particularly when much insulin is used, and also probably exerts a mild stimulating effect upon carbohydrate tolerance for the following meal.

Diet Prescriptions.—The following diets are employed on the metabolic service at Sea View Hospital:

<i>Diet.</i>	<i>Carb.</i>	<i>Prot.</i>	<i>Fats.</i>	<i>Calories.</i>
Low carbohydrate.	100	90	160	2050
Medium carbohydrate No. 1.	130	90	100	1700
Moderate carbohydrate No. 2.	150	90	120	1950
High carbohydrate No. 1.	200	90	110	2050
High carbohydrate No. 2.	250	90	120	2400

Insulin.—This hormone has radically altered the treatment and prognosis of diabetics with tuberculosis. It is now possible to quickly desugarize the diabetic without restricting

the diet. Its use is indicated in all cases of diabetes not easily controlled by moderate carbohydrate restriction, and especially where malnutrition is present. In these cases, insulin should be employed without delay to permit assimilation of a high caloric diet.

There are no valid contraindications to the use of insulin. Focal pulmonary reactions^{11, 12} first reported were probably due to protein impurities. Although insulin reactions occasionally occur, there is no evidence that such reactions exert any disastrous effect upon the pulmonary disease.

The customary procedure for the administration of insulin is followed. Severe diabetics require two or three injections, the larger one before breakfast to check the high blood sugar usually present at that time. The smallest dose is given before lunch. In very severe cases of diabetes, a small injection is often necessary at night about 9 P. M. to check the rising blood sugar during the night and early morning hours. The recently introduced modifications of insulin with retarded absorption and prolonged effect may reduce the number of required injections in such cases.

The total insulin dosage varies with the severity of the diabetes ranging from 10 units in very mild cases to about 150 in very severe instances. One refractory case required as much as 400 units daily. Young diabetics and those with endocrine disorders of the thyroid, pituitary and sex glands are the most difficult to control, and require the largest amounts of insulin.

Because of vagaries of appetite and food intake, it is not desirable to administer more than 30 or 40 units of insulin at one time, lest hypoglycemic reactions occur. In cases requiring large and frequent doses of insulin, it is advisable to follow the sequence of events closely by sugar determinations of postprandial urine specimens. This reveals the efficiency of the individual dose of insulin, in relation to the available carbohydrates in each meal. Glycosuria means that the insulin has not been effective in preventing the blood sugar from rising above the renal threshold (usually 160 to 180 mg. per 100 cc.). It therefore indicates either an increase of insulin

or a reduction in the carbohydrate content of the individual meal. In many instances, glycosuria occurs only during part of the day and can only be localized by divided urine examinations.

Local insulin reactions occasionally occur, but are seldom severe and usually disappear spontaneously or when another brand of insulin is substituted. They are allergic manifestations which must not be confused with true insulin reactions or hypoglycemia. Crystalline insulin, free of protein impurity, is now available for such cases.

Hypoglycemia.—Hypoglycemic insulin reactions are frequent in tubercular diabetics. This is due to various causes, of which the following are the most frequent:

1. Tubercular patients suffer from marked variations in appetite, as well as frequent gastro-intestinal upsets. Lack of ingestion of the expected quota of carbohydrate may precipitate hypoglycemic reactions especially if large amounts of insulin are being used.

2. The average mild diabetic on proper treatment undergoes a progressive improvement in carbohydrate tolerance that is often astonishing. Unless this natural change is recognized and anticipated by reduction in insulin, or increase in the carbohydrate intake, insulin reactions may supervene.

3. Patients who have previously been confined to bed may develop hypoglycemic reactions due to the improved carbohydrate tolerance resulting from increased muscular activity.

It has been stated previously that insulin reactions do not exert any obviously injurious effect upon the pulmonary tuberculosis. This does not mean, however, that hypoglycemia is without danger. On the contrary, a sharp reduction in blood sugar is distinctly dangerous, particularly in middle-aged individuals with coronary sclerosis and myocardosis, as emphasized by Levine,¹³ Sherrill¹⁴ and others.

The treatment of hypoglycemia consists in the administration of fruit juice or dextrose, syrup by mouth, as soon as the premonitory symptoms—sweating, giddiness, diplopia, etc.,

develop. Unfortunately, the symptoms are extremely variable, and the condition may not be recognized until the individual is in coma. In such instances, glucose intravenously and adrenalin are urgently necessary.

The Blood Sugar.—Very little consideration has been given so far in this discussion to the blood sugar level as a criterion of satisfactory control of diabetes. Although a more accurate gauge of conditions than the urine, the blood sugar has proved of limited practical value. This is due to the impracticability of obtaining frequent blood sugar determinations and the necessary delay in receiving the results of these analyses from the laboratory. Urine specimens, however, can be collected without difficulty and the sugar determined immediately.

For practical purposes, the blood sugar is of little clinical value as long as glycosuria persists. Glycosuria in a proved case of diabetes is sufficient evidence of a high blood sugar (at least over 160 mg.). Only when glycosuria disappears is the blood sugar level of any clinical value. Fasting morning specimens, or postprandial blood sugar determinations may then be used to gauge the efficacy of treatment. Progressive reduction in blood sugar suggests improvement, while continued increase indicates diminishing tolerance preceding glycosuria.

Much controversy has centered upon the significance of persistently elevated blood sugar levels without glycosuria. Most investigators, including Mosenthal^{15, 16, 17, 18} and MacLeod¹⁹ do not believe that elevated blood sugar levels without glycosuria, are in themselves dangerous or responsible for the symptoms, sequelae, or complications of diabetes. Nor is there any proof that blood or tissues of increased sugar content favor the growth of organisms or are less viable²⁰ or resistant to infection than normal.²¹ The lowered local and general resistance of uncontrolled diabetes is probably attributable to the desiccation and perverted tissue metabolism of this disease.

It follows that although a relatively normal blood sugar, especially in younger people, is desirable, this objective must

not be made a fetish to the detriment of the patient. Especially in older people, a moderate hyperglycemia (without glycosuria) is harmless,¹⁸ and probably necessary²² and excessive efforts to lower it must be avoided.^{14, 23} Strouse^{24, 25} observed cardiac symptoms, including fibrillation, block and angina following the reduction of previously elevated levels of blood sugar. Due to a high renal threshold, older diabetics frequently exhibit no glycosuria, with fasting blood sugar levels of 200 mg. or over.

Acidosis.—Severe acidosis is rarely seen except in young diabetics; slight degrees of ketosis may develop in mild diabetics due to intercurrent infection, gastro-intestinal upset, or in the presence of an acute pulmonary episode, especially hemoptysis.

In such cases, all other treatment becomes secondary until the ketosis and acidosis have been corrected. Frequent injections of insulin should be given, checked by urinary sugar and acetone determinations. If signs of ketosis persist, but glycosuria disappears, then insulin and glucose should be given intravenously. Fluids are forced by all channels to overcome the marked dehydration.

Not infrequently, diabetic patients seen for the first time in acidosis and coma are later found to be suffering from tuberculosis. The importance of acidosis in predisposing to subsequent pulmonary tuberculosis has already been emphasized.

The Influence of Pulmonary Tuberculosis Upon Diabetic Tolerance.—Tuberculosis appears to be an exception to the general rule that infections lower sugar tolerance in diabetes. Often, chronic tuberculosis exerts no appreciable effect upon the course of diabetes.

Many clinicians have noted the apparent benign influence of extensive progressive tuberculosis upon sugar metabolism in diabetes.

Joslin¹ states that when the diabetes is apparently improving, but the patient doing poorly and losing weight, suspect tuberculosis. Naunyn,²⁶ and others,²⁷ have reported instances

of distinct improvement in sugar tolerance of diabetic patients suffering from advanced tuberculosis. Lundberg²⁸ postulated secretion of an insulin-like hormone (para-insulin) by tuberculous tissue. It seems likely, however, that more tangible factors account for this effect.

1. In many instances, the changes noted appear to be no more than the normal increase in carbohydrate tolerance occurring in diabetics following desugarization and stabilization.

2. In severe terminal cases of tuberculosis, the explanation probably lies in the associated malnutrition. As emphasized by Allen,²⁹ undernutrition in itself exerts a decidedly beneficial effect upon carbohydrate tolerance. Prior to the introduction of insulin, undernutrition was a recognized method of treatment in diabetes. Marked improvement in sugar tolerance is very frequently observed in advanced or terminal cases, but inanition, weight loss, and restricted food intake, are invariably present. Many cases previously requiring large doses of insulin to prevent glycosuria, become sugar free without any insulin. True instances of improved tolerance due to advancing tuberculosis, without inanition, are rare. Only one case that may fit in this category has been noted on our service in the last five years.

It is not always true, however, that extensive pulmonary tuberculosis is without effect upon the carbohydrate tolerance. Glycosuria often appears in diabetic patients, following hemoptysis and extensive pulmonary or hematogenous spread, especially if associated with toxemia and elevated temperature. Such cases may pass quickly into acidosis or coma. Pleural effusions, sterile or purulent, often exert a deleterious effect upon sugar metabolism.³⁰ In some instances on our service, this complication was suspected because of unexplained glycosuria.

Treatment of Pulmonary Tuberculosis in Diabetes.—

No attempt will be made to cover this aspect of the subject which is exhaustively dealt with elsewhere. The usual indications for treatment of pulmonary tuberculosis apply. Age and frequency of vascular and coronary disease are the main

modifying factors that restrict application of surgical procedures. The fact that 85 per cent of pulmonary lesions discovered in diabetics are at an advanced stage, also necessarily modifies therapeutic indications and prognosis.

Probably the best results from surgical measures such as pneumothorax and thoracoplasty, are obtained in young diabetics, despite the severity of the associated diabetes. The reason is obvious, since such individuals have had less opportunity to develop general arteriosclerosis and other complications that are frequent in older diabetics. Often the status of the cardiovascular system in older diabetics precludes any surgical intervention whatsoever. Pneumothorax sometimes causes severe anginal symptoms in individuals with coronary sclerosis, and occasionally congestive cardiac failure has been noted. Dyspnea and orthopnea are frequent in cases with coronary sclerosis when extensive bilateral pulmonary involvement limits vital capacity.

Prognosis.—At one time the association of diabetes and tuberculosis was considered an invariably fatal combination.^{31, 32} The introduction of insulin has markedly altered the immediate prognosis.^{33, 34, 35} The diabetes can be controlled without great difficulty and very few cases die from that alone. The improvement in nutrition that follows insulin and an adequate diet favorably influences resistance to the pulmonary infection. Given a relatively early pulmonary infection, the prognosis in diabetics differs little from that in other patients.³⁶

Unfortunately most cases of pulmonary tuberculosis in diabetes are seen at a relatively advanced stage of the disease. The problem involved is the treatment of a middle-aged group of individuals, usually with extensive pulmonary tuberculosis, and often suffering from the sequelae of poorly controlled diabetes; namely, vascular and cardiac disease. As long as the diagnosis of pulmonary tuberculosis is made at a very advanced stage of the disease in diabetics, the prognosis will remain poor. The immediate life expectancy following diagnosis

has probably been materially improved by modern methods of treatment.

CLINIC OF DR. RALPH F. HARLOE

SEA VIEW HOSPITAL

TUBERCULOUS EMPYEMA: A PRELIMINARY OUTLINE ON THE FORM OF TREATMENT EMPLOYED ON THE SURGICAL SERVICE OF THE SEA VIEW HOSPITAL

THORACIC empyema, which frequently follows lobar or bronchopneumonia, and empyema complicating pulmonary tuberculosis, present two entirely different clinical pictures.

In the former, we as a rule entertain no misgivings relative to the favorable outcome of the infection in uncomplicated cases. Generally, we are dealing with a pleural space in which the lung has been completely expanded until the advent of the pleural effusion, which, as it increases in volume, causes compression and displacement of the lung, heart and mediastinum.

If one were to slowly aspirate the purulent effusion, at the same time preventing air from entering the pleural space, the lung, owing to its elasticity, would expand as the effusion was withdrawn and at the end, would again fully return to its normal position.¹

In tuberculous pyogenic empyema, we are confronted by a more serious problem which presents a vastly different and a more dismal clinical picture than does the usual postpneumonic empyema. Its successful treatment has been one of the most baffling combats with which the thoracic surgeon has had to deal.

Before thoracic surgery became one of the great factors in the treatment of pulmonary tuberculosis, patients afflicted with tuberculous pyogenic empyema were operated upon by costectomy, followed by the insertion of a large drainage tube several inches in length. Purulent drainage continued for months or

years and recovery was of rare occurrence, even in patients with arrested lesions and negative sputum. This type of operation alone was in itself sufficient to prevent sterilization of the pleural cavity.

Once the thoracic cage is opened and a drainage tube inserted, secondary infection is a constant factor. If the patient did not succumb from active spreading tuberculosis, he died from a progressive generalized amyloid disease as a result of prolonged chronic sepsis.

The apparent hopelessness of these patients stimulated thoracic surgeons to exhaust every means in an effort to sterilize the pleural cavity and thus effect a cure. Various dyes were employed as well as gomenol in oil. Sterile filtered ox bile was also one of the many substances added to the list of remedies which were injected in quantity into the infected pleural cavity.

Today, if costectomy with simple drainage was employed, it would offer no brighter prognosis than in the earlier periods, unless an effort was made to reduce the toxemia by frequent irrigation of the empyema cavity, and to build up the patient with frequent blood transfusions to a point where, by thoracoplasty or Schede's operation, an attempt could be made to obliterate the cavity and cure the empyema.

It is the general opinion that to cure an empyema, whether tuberculous or postpneumonic, we must first be rid of the empyema cavity.

CLASSIFICATION

We cannot fully present the subject of tuberculous empyema without first discussing so-called "simple" tuberculous empyemas. These patients remain on the medical service under the care of the medical director and his staff.

Aspiration is not done unless the patient becomes embarrassed by accumulation of the effusion which may be sterile on culture but reveals tubercle bacilli on stained smears.

All pyogenic tuberculous empyemas admitted to the surgical service were at one time included under the simple form.

Mixed infection empyema may result from:

1. Contamination from without during paracentesis.
2. Tuberculization of needle tract followed by fistulization.
3. Spontaneous pneumothorax with bronchial fistula.
4. Empyema necessitatis with discharging sinus.
5. Rupture of a tuberculous cavity into the pleural space following a closed pneumolysis (Jacobaeus). Rupture of a tuberculous excavation into the pleural cavity is generally followed by a fetid anaerobic empyema.

TREATMENT

At Sea View Hospital certain fixed rules have been promulgated for the treatment of tuberculous empyema.

All such patients when transferred to the surgical service are individualized and treatment accorded as may fit each one.

Patients with simple tuberculous empyema and *bronchial fistula* with no evidence of pyogenes either by culture or stained smear of the pleural effusion are recommended for thoracoplasty.

These patients sooner or later will develop a pyogenic tuberculous empyema and an early thoracoplasty will forestall this complication with its associated toxemia.

When the presence of a bronchial fistula is suspected and before any type of operative treatment is instituted, a small quantity of methylene blue solution is injected in the pleural cavity and the sputum examined during the next forty-eight hours for the presence of the dye.

Occasionally patients are admitted to the empyema service with a temperature ranging between 99° and 103° F. Exploratory thoracentesis reveals an extremely thick exudate from which no growth is obtained on culture, but when a stained smear is examined, numerous tubercle bacilli are found, together with a moderate number of unidentified organisms which may be anaerobes, but not of the group that are found in putrid empyema or lung abscess.

Treatment of these cases consists in placing the patient in a sitting posture and inserting an aspirating needle on the an-

terior axillary line through an interspace corresponding to the lowest point of the empyema cavity. After all of the thick exudate has been aspirated, the cavity is then thoroughly irrigated through the needle with warm normal saline solution, until the return washings are clear.

When this is accomplished, the patient lies down with the affected side uppermost, and from 200 to 450 cc. of 1:3300 azochloramide solution is injected in 50 cc. quantities through the needle into the pleural cavity. As the fluid level rises, air is displaced through the needle while the syringe is being re-filled. The needle is then withdrawn and the puncture wound covered with collodion. This procedure is repeated daily for from seven to ten days. The temperature usually falls to normal in from forty-eight to seventy-two hours.

About one week later a needle is again inserted into the previously treated cavity and a small amount of fluid aspirated for examination. Stained smear reveals no tubercle bacilli or other bacteria and the effusion is either a clear amber color or a slightly cloudy, thin fluid.

Two patients among those recently treated by this procedure presented an empyema necessitatis, one patient revealing two anterior and one posterior fluctuating areas which were very painful on pressure.

Following treatment by aspiration at only one point on the anterior axillary line, plus azochloramide instillation, the fluctuating areas rapidly disappeared and were no longer a factor.

Because of the presence of organisms noted on direct smear in addition to tubercle bacilli, we have placed these patients in the class with mixed infection empyemas.

The reason for so doing is that occasionally a patient does not respond to the aspiration and instillation treatment and a closed thoracotomy is then performed.

All of our cases of mixed tuberculous empyema receive this treatment which consists in inserting a No. 18 or 20 mushroom catheter by means of a trochar and cannula, through the eighth or ninth intercostal space, employing local anesthesia. The anterior axillary line is selected in order that the

thoracotomy wound will not be near the line of incision if thoracoplasty is later performed.

After the catheter has been withdrawn until the tip is in contact with the parietal pleura, a Harloe empyema disk is then slid over the tube until it reaches the skin. The disk is then fastened to the skin by adhesive plaster.

Postoperative Treatment.—*Empyema without Bronchial Fistula.*—The catheter is connected by means of a glass Y tube to two 4-foot lengths of rubber tubing, one of which leads to a graduated irrigating bottle suspended from a stand beside the bed and filled with the irrigating solution (saline, azochloramide or chlorazene solution). The other tube passes into a bottle containing a small quantity of water to act as a water seal. The bottle is placed on the floor. The distal end of the second tube is connected to a 12-inch piece of glass tubing which passes through a 2-hole rubber stopper so that the lower end of the tube lies beneath the surface of the water for the distance of $\frac{1}{2}$ inch.

As the fluid in the bottle rises, the glass tube is elevated so that the tip will not reach too far beneath the fluid level.

Every four hours the empyema cavity is irrigated, while the patient is supported in the sitting posture.

First, the outflow tube is compressed, and when the clamp is removed from the inflow tube, irrigating solution in 100 cc. quantities is permitted to alternately flow into the pleural cavity and thence into the bottle on the floor. This is continued until the return washings are clear. The inflow tube is then clamped and the outflow tube permitted to remain open.

During irrigation, the weight of the column of fluid in the outflow tube extending from the Y tube to the surface of the fluid in the bottle on the floor, exerts sufficient negative pressure to completely remove all washings from the empyema cavity.

The above postoperative treatment is modified to fit the individual case.

Pyogenic Tuberculous Empyema with Bronchial Fistula.

—No intermittent irrigation with negative pressure, as above described, is done.

The catheter instead is connected to a piece of rubber tubing about 2 feet long, the distal end of which passes into a liter bottle fastened to a side bar of the bed so that it hangs just below the level of the mattress. No water is placed in the bottle. The tube is left open at all times and at the end of every four hours the catheter is disconnected from the outer tube and 100 cc. quantities of warm saline solution are injected into the pleural cavity and then permitted to run out by gravity into a basin. Instillations are continued until the washings return clear. The catheter is again connected to the second tube so that further drainage between irrigations passes into the bottle.

If the saline solution was withdrawn with the syringe, instead of being permitted to flow out by gravity, the negative pressure occasioned by traction on the piston is likely to cause alternate opening and closing of the fistula, thereby delaying healing.

Postpneumonic empyemas managed in this fashion permit healing of the bronchial fistula in from six to fifteen days.

Anaerobic Tuberculous Empyema.—These patients are desperately ill and frequently become cyanotic and dyspneic immediately following rupture of the tuberculous cavity as the result of tension pneumothorax caused by a ball-valve action at the site of the ruptured cavity, which permits air to enter the pleural cavity on inspiration but prevents its exit. When confronted with such complications, the case becomes emergent and relief must be speedily administered.

The set-up for a closed thoracotomy must be made ready. In the interval, a large caliber aspirating needle should be inserted under local anesthesia, into the pleural cavity above the fluid level, to relieve any intrathoracic tension that might be present.

The needle should not be removed until everything is in readiness to insert the tube. Too long an interval between removal of the needle and insertion of the thoracotomy catheter

will result in a recurrence of tension pneumothorax. At this time, however, air and anaerobic pus will be forced into the needle opening recently made in the parietal pleura, causing a diffuse subcutaneous emphysema and resulting in a phlegmonous cellulitis of the chest wall, with possibly fatal termination.

The technic of closed thoracotomy and postoperative treatment for the anaerobic empyema, is the same as described under "Empyema with Bronchial Fistula."

Because of the extreme toxemia following anaerobic empyema, irrigation at four-hour intervals with 50-cc. instillations of warm normal saline solution, is most important. The relatively small quantity of saline employed does not enter the bronchus, particularly if the patient is supported in a high Fowler position. Not only does frequent irrigation cause thinning of the pus and favor drainage, but in addition it keeps the pleural cavity cleaner, thus reducing to a great extent absorption of toxins.

The disagreeable foul odor of the pus may in part be overcome if Dakin's sodium hypochlorite solution is placed in the bottle which is tied at the side of the bed to receive the drainage.

Further treatment consists in giving daily intravenous glucose and saline and a blood transfusion of from 250 to 400 cc. every fourth or fifth day.

Postpneumonic empyemas with bronchial fistula and anaerobes rapidly recover when treated in the above manner. The tuberculous patient, if promptly treated, should in a very short time overcome the anaerobic infection and be included in the list of pyogenic empyemas with bronchial fistula.

The treatment of mixed infection tuberculous empyema having been outlined, the question now arises as to whether, by the application of such treatment, the patient continues to improve and finally arrives at a point where, without further treatment, the empyema is cured.

As previously stated, no pyogenic tuberculous empyema is cured while the empyema cavity still exists.

Thoracoplasty.—The treatment by thoracotomy and irrigation is only the preliminary step. The next step is to eradicate the cavity by a two- or three-stage thoracoplasty. Every effort is made to treat the empyema at its inception and continue thereafter by systematic irrigation and supportive treatment to improve the general condition of the patient, to the point where he is a safe risk for thoracoplasty.

If one were to wait several weeks or months before attempting thoracoplasty, the continued irritation resulting from the infection within the pleural cavity would cause the pleura to become densely thickened, so that a Schede operation might be necessary.

Thoracoplasty must be done at as early a stage as the condition of the patient will permit. Many patients are thus cured.

If the final result is a small superficial discharging sinus, we should feel that much has been accomplished in what would have been in the earlier days a hopeless situation.

It is unfortunate that a large number of patients have extensive bilateral lesions and many are retrogressing. When empyema is added to such an apparently hopeless picture, a thoracotomy with supportive treatment is carried out, but all efforts fail to arrest the caseous-pneumonic pathology and these patients rapidly succumb.

There is, however, a less unfortunate group of patients with bilateral lesions, some of which are being controlled by selective pneumothorax.

A pyogenic empyema superimposed upon one or the other side, would of necessity require a longer period of treatment. Thoracoplasty would be contraindicated until such time as the lesion in the contralateral lung could be controlled by artificial pneumothorax, a selective pneumothorax being continued as outlined by Coryllos and Ornstein² in the management of bilateral tuberculosis.

In many patients the added sepsis of an empyema changes an apparently favorably progressing course to a rapidly changing down-hill course, finally ending in death.

Even in unilateral caseous-pneumonic tuberculosis complicated by pyogenic empyema, it is at times impossible by any means to improve the general condition of the patient or to arrest the parenchymal tuberculous activity in the involved lung, so that thoracoplasty might come to his aid.

SUMMARY

1. Pyogenic tuberculous empyema is a frequent and dismal complication of pulmonary tuberculosis.
2. All cases should be given the benefit of early thoracotomy.
3. With no contraindications, thoracoplasty should be performed as soon after the onset of the empyema as possible.
4. Patients with simple tuberculous empyema and bronchial fistula should receive thoracoplasty before they are complicated by mixed infection.
5. All cases of pyogenic tuberculous empyema with bronchial fistula, either aerobic or anaerobic, should be operated upon by thoracotomy with open tube and receive saline irrigation every four hours.
6. Frequent blood transfusion is by far the best therapeutic agent to improve the general condition of the patient before operation.

CLINIC OF DRS. IRVING GRAY AND IRVING GREENFIELD

FROM THE DEPARTMENT OF MEDICINE, SEA VIEW HOSPITAL

GASTRO-INTESTINAL SYMPTOMS IN PULMONARY TUBERCULOSIS*

GASTRO-INTESTINAL symptoms in patients with pulmonary tuberculosis may be due either to functional disturbances, or organic changes in the alimentary canal. Pyrexia, disturbance of the vegetative nervous system, and emotional factors all play a part in the production of gastro-intestinal symptoms. When these factors come into play, we have the disturbance on a functional basis. Gastro-intestinal symptoms may occur in patients with pulmonary tuberculosis based on reflex mechanisms before there is any organic change in the intestinal tract. Abdominal symptoms due to ulcerative processes in the intestinal canal by the tubercle bacillus are rather frequent.

Literature.—The association between digestive disturbances and pulmonary tuberculosis has long been known. Brown and Sampson, who have contributed much of interest and importance to this subject, divide the history of intestinal tuberculosis into four periods.

1. "The dysentery period during which it was noted that diarrhea frequently occurred late in the course of pulmonary tuberculosis, but little consideration was given to the fact that it might be due to the same disease in a different organ. This, the period of clinical observation, extended from the time of Hippocrates to that of Bayle (1810).

* We are indebted to Dr. Oscar Auerbach, Pathologist, at the Sea View Hospital for his cooperation

2. "The period of 'tuberculous diarrhea,' during which the lesions in the intestine were described and noted as tuberculous and the diarrhea definitely connected with them. This period of pathological observation extended from the time of Bayle (1810) to the time of Louis and Rokitansky (1825-1842).

3. "The period of pathological study during which the pathological changes were fully described and attempts made to connect the varying symptoms with the various changes in the lesions found at postmortem. The diagnosis during life was always uncertain. This period of pathological study lasted from the time of Louis and Rokitansky to 1919.

4. "The period of 'roentgenological diagnosis,' during which the diagnosis and consequently the scientific study and scientific treatment of intestinal tuberculosis could be accurately pursued, dated from the roentgenological diagnosis of intestinal tuberculosis and was placed on a firm foundation in 1919, by the work of the above authors at the Trudeau Sanitarium."

We have been interested in correlating the physical examination and clinical symptomatology with the findings on postmortem examination. At this clinic session, we desire to bring to your attention the predominant clinical symptoms and the findings on physical examination in correlation with the autopsy findings in a comparative study of 100 patients who died of pulmonary tuberculosis. For this study we have selected 100 consecutive records of patients who have died at the Sea View Hospital and we have analyzed the pathological protocols and the clinical charts. The Sea View Hospital is a municipal hospital for tuberculosis and all those eligible for free service, irrespective of color, creed or nationality, are admitted.

CHART 1

INCIDENCE OF PULMONARY TUBERCULOSIS IN RELATION TO AGE

	White.		Colored.	
	Male.	Female.	Male.	Female.
Incidence.....	37.0	25.0	20.0	18.0
Average age.....	40.7	23.7	33.8	26.7
Youngest.....	13.0	13.0	22.0	13.0
Oldest.....	65.0	49.0	67.0	49.0

All of our patients had pulmonary tuberculosis. Many entered the hospital with far advanced tuberculous disease which terminated fatally soon after admission. Seventy-nine per cent of the patients had pathological evidence of tuberculosis of the alimentary canal as well as evidence of tuberculosis of the accessory organs of digestion. In the remaining 21 per cent of cases careful gross and microscopic study failed to uncover evidence of gastro-intestinal tuberculosis.

The symptoms manifested by our group included general digestive disturbances, loss of appetite, nausea, vomiting, pain and discomfort in the abdomen, constipation, diarrhea and pain on swallowing.

General Digestive Disturbances.—Under this heading were grouped those patients with complaints which were vague and which Friedenwald and Morrison¹ have classified as dyspepsia. They embraced the following:

Distress after eating	12
"Sour stomach"	8
Acid eructations	7
Heart burn	1

In one case a diagnosis of gastric ulcer was made four years before the onset of pulmonary tuberculosis. The digestive symptoms referable to the ulcer were intensified by the intestinal tuberculosis. There was no evidence of tuberculosis of the stomach in this patient at autopsy. Tuberculous ulcer of the stomach is exceedingly rare. In Goldberg's² series, it occurs in 0.6 per cent of cases. In our studies there was no case of primary tuberculous ulcer of the stomach. In the case cited a few tubercle bacilli were found in the margin of the existing peptic ulcer.

Appetite.—While loss of appetite is not characteristic of gastro-intestinal tuberculosis 26 or 33 per cent of our cases noted a decided loss of appetite. Eight or 10 per cent of the patients noted that there was no alteration in their appetite and 4 or 5 per cent listed their appetites as fair. Friedenwald and Morrison¹ noted loss of appetite in 28 per cent and a normal appetite in 10 per cent of their cases.

Nausea.—Nausea is not an uncommon symptom and is often associated with loss of appetite and vomiting. It occurred at different times of the day and was not consistently related to meals. Brown and Sampson³ reported an incidence of 52 cases in their series of 100 patients selected for study. Friedenwald and Morrison¹ noted that it occurred in 18 of their 50 patients. In our series nausea occurs in 18 or 25 per cent of the patients.

Vomiting.—This symptom occurs with or without nausea. Not infrequently vomiting follows a spell of coughing and occasionally follows meals. When at the latter time, the food is ejected in an undigested state. Fenwick⁴ recorded the incidence of vomiting in 32 per cent of his series. Brown and Sampson³ noted vomiting in 37 per cent of their cases. Erickson⁵ noted vomiting in 37 per cent of his cases. In our series of 100 patients vomiting occurred in only 23 per cent. It occurred following coughing in 6 patients. In only one case was the vomiting listed as severe.

Pain and Abdominal Discomfort.—Abdominal pain is not a frequent complaint in the advanced stages of gastrointestinal tuberculosis. It may be referred to the epigastrium or right lower quadrant, and may be characterized as cramp-like or even colicky in nature. As a rule it is not severe pain but is usually referred to as "a soreness," deep, aching or vague in character. The timing of the pain was not accurate and occurred at variable times of the day and night, somewhat more frequently following meals as a "distress," but occasionally in the interval between meals. Engelsmann⁶ noted pain in 22 per cent of his cases. Fenwick⁴ recorded the incidence of pain as occurring in 41 per cent of his series, while Friedenwald and Morrison¹ noted an incidence of 86 per cent. Brown and Sampson³ found that 7 per cent of their patients had no pain until late in the disease. In our series of cases 92 per cent complained of abdominal pain or some form of abdominal discomfort. Fifteen per cent of patients did not note abdominal discomfort until the terminal stage of the disease.

Disturbance of the Bowels.—Constipation of varying degree was noted in an appreciable number of cases. While constipation is common early in pulmonary tuberculosis occasional attacks of diarrhea may occur. Constipation may be followed by diarrhea or one may have alternating constipation and diarrhea as was noted by Burnand and Perret.⁷ Lebert⁸ was of the opinion that diarrhea without ulceration occurred in from one tenth to one seventh of all cases coming to necropsy. It is beyond the scope of the present discussion to attempt a description of the stools in intestinal tuberculosis. As a terminal event the diarrhea may be intractable and not infrequently resists any and all treatment. In itself, it may influence the course of the disease. Disturbed bowel function was noted in 28 per cent of our cases in the advanced stages of the disease.

Chart 2 indicates the incidence of general symptoms not referable to the gastro-intestinal tract in our series of cases. For purposes of future reference it is necessary to note the incidence in both sexes of the white and negro races separately.

CHART 2

CLINICAL SYMPTOMS (OTHER THAN GASTRO-INTESTINAL) IN PULMONARY TUBERCULOSIS

	<i>White.</i>		<i>Colored.</i>	
	<i>Male.</i>	<i>Female.</i>	<i>Male.</i>	<i>Female.</i>
Contact	6	5	0	4
Cough . .	21	21	12	14
Expectoration	11	15	8	9
Hemoptysis	9	9	4	3
Chills .	7	1	1	1
Fever	14	7	3	8
Sweats	14	5	6	8
Dyspnea	7	3	2	3
Fatigue	22	18	6	12
Weakness	20	15	8	10
Loss of weight	17	17	11	9
Average loss of weight	4.6 lbs. per mo.	3 lbs. per mo.	4 lbs. per mo.	5 lbs. per mo.

Physical Examination.—Edwin Klebs,⁹ in 1868, was the first to call attention to the fact that intestinal tuberculosis secondary to pulmonary tuberculosis was almost always due

to swallowing of the tubercle bacilli. Tubercle bacilli were present in the sputum of 85 per cent of our cases. Williams and Gardner¹⁰ found pulmonary cavitation in 88 per cent of 169 cases. In our series, 41 patients or 52 per cent had a caseous-pneumonic form of tuberculosis according to the classification of Ornstein, Ulman and Dittler.¹¹ The incidence of positive sputum in our group was 73 per cent as against 27 per cent of the patients with cavitation who failed to show tubercle bacilli on repeated examination. The sputum ranged from Gaffky 3 to Gaffky 10 in the cases of caseous-pneumonic pulmonary tuberculosis. In the cases of chronic pulmonary tuberculosis without pathologically demonstrable cavities the Gaffky count was from 2 to 5.

Temperature.—The temperature chart of patients with secondary gastro-intestinal tuberculosis does not conform to any particular or characteristic pattern. It may be normal, low grade, or septic in type. In 30 of our patients (38 per cent), the temperature was characterized as septic; 43 of the patients (54 per cent), ran a low-grade fever, and in 27 patients (34 per cent), there was no elevation of temperature at any time during the course of the disease.

Gastric Analysis.—Hausman,¹² Bassler,¹³ Gray and Ornstein,¹⁴ Levy and Kantor,¹⁵ Granet and Ornstein¹⁶ have reported on the gastric findings in pulmonary tuberculosis. Gastric extraction was performed in 9 of our patients. Tubercle bacilli were found in the centrifuged sediment of 4 patients and were not found in the centrifuged sediment of 5 patients. All of the patients whose gastric contents contained tubercle bacilli were females. No attempt is made at this time to discuss the relationship of sex and duration of the tuberculous process to the gastric acidity. Gray and Melnick¹⁷ have reported that tubercle bacilli in gastric washings are found more frequently in the female than in the male patients. This may be accounted for by the fact that the female because of her social habits may be less inclined to expectorate and swallows the sputum. These authors point out that the

presence of hydrochloric acid in the gastric secretions is a factor.

Stool.—The value of tubercle bacilli in the stool of patients with tuberculosis has been much disputed. Lichtheim,¹⁸ Rittel-Willenke¹⁹ and Gant²⁰ and others adhere to the school which contends that the isolation of tubercle bacilli from the stool constituted positive proof of the presence of intestinal tuberculosis. On the other hand, the work of many excellent investigators such as Biermann²¹ and Klose²² has shown that tubercle bacilli may be found in patients without evidence, even at postmortem, of intestinal tuberculosis. The presence of tubercle bacilli in the sputum is held as an important factor. The bacilli which are swallowed pass through the gastro-intestinal tract without producing any pathological changes. In our series 17 patients had stool examinations for tubercle bacilli. In 9 patients bacilli were found and in 8 patients no organisms were found.

Abdomen.—Abdominal examinations are of questionable value in establishing a diagnosis of a complicating gastro-intestinal tuberculosis. Careful examination may reveal some thickening of the cecum or a mass in the right lower quadrant. There may be pain or tenderness over the area of involved intestine. It should be borne in mind that marked tenderness and rigidity usually signify involvement of the peritoneal surface of the affected portion. In 84 per cent of our patients the abdomen was noted soft, distention was recorded in 11 per cent and tenderness was noted in 12 per cent. The abdomen was reported as doughy twice and there was moderate voluntary spasm three times. Ascites was noted in 3 patients. The liver was palpable and soft in 10 patients and the spleen was easily felt in 6 patients. On two occasions splenomegaly was noted without enlargement of the liver and on three occasions the liver was enlarged without evidence of splenomegaly. Fistula in ano was reported in 1 patient.

Chart 3 indicates the distribution of the lesions as found at postmortem.

CHART 3

PATHOLOGICAL FINDINGS IN ONE HUNDRED AUTOPSIES (79 PER CENT WITH GASTRO-INTESTINAL TUBERCULOSIS)

	<i>Number of cases.</i>	<i>Per cent.</i>	<i>Goldberg's percentage based on study of 179 cases.</i>
Tongue.....	2	2.5	0.6
Stomach.....	1	1.2	0.6
Duodenum.....	7	8.8	3.8
Jejunum.....	24	30.3	21.8
Ileum.....	62	78.4	83.2
Cecum.....	62	78.4	87.0
Appendix.....	21	26.5	39.1
Ascending colon.....	43	54.4	
Transverse colon.....	26	32.9	
Descending colon.....	17	21.5	
Rectum.....	6	7.5	

For purposes of comparison we have used the per cent incidence as noted by Goldberg.² We were unable to record the comparative statistics of the incidence of tuberculous involvement of the colon because in our series the colon was divided into three parts, the ascending, transverse and descending portions. The presence of ulceration was listed in each part individually. We therefore have overlapping and could not compare the incidence of tuberculous ulceration of the colon in our series with that reported by Goldberg.

CHART 4

PATHOLOGICAL FINDINGS (IN ONE HUNDRED AUTOPSIES—79 PER CENT WITH GASTRO-INTESTINAL TUBERCULOSIS) IN ACCESSORY DIGESTIVE ORGANS

	<i>Incidence.</i>	<i>Per cent.</i>
Mesenteric lymph nodes	39	49.3
Peritonitis.	9	11.4
Liver.	35	44.3
Gallbladder.	1	1.2
Bile ducts.	2	2.5
Spleen.	38	48.1
Adrenals.	4	5.0

In the one case of tuberculosis of the gallbladder there was associated tuberculosis of the gastro-intestinal tract. Jaundice was not present in either of the two cases of bile duct tuberculosis. In one of these there was associated tuber-

culosis of the gastro-intestinal tract. In the other tuberculosis of the bile duct was the only evidence of tuberculosis in the abdominal cavity.

Comment.—In view of the fact that 79 per cent of these patients had evidence of multiple lesions in the gastro-intestinal tract, it is difficult to correlate with any degree of certainty the relationship between the clinical symptoms and the pathological findings. Vomiting occurred in 23 per cent of the group, nausea in 25 per cent, general digestive disturbances in 28 per cent, bowel disturbances (constipation and diarrhea) in 28 per cent, loss of appetite in 33 per cent and varying degrees of abdominal pain and discomfort in 92 per cent. It is evident that practically all of the patients had some abdominal complaints. The intensity, duration and character of the abdominal symptoms are quite variable and bear no direct relationship to the pulmonary process and to the pathological lesions present in the gastro-intestinal tract. In this group of 100 patients with pulmonary tuberculosis, 79 per cent had pathological changes in the gastro-intestinal tract and 21 per cent had no demonstrable lesions, gross or microscopic, of tuberculosis.

CLINIC OF DR. POL N. CORYLLOS

DEPARTMENT OF THORACIC SURGERY, SEA VIEW HOSPITAL

A NEW CONCEPTION OF THE MECHANICS AND PHYSIOLOGY OF COUGH

(Action of Diaphragm in Cough)*

COUGH reflex has become of major interest to the thoracic surgeon. Cough is at the same time a "watch-dog" of the bronchial tree, as Jackson named it, and one of the most powerful factors of dissemination of pulmonary infections. Its suppression during the immediate postoperative period favors the accumulation and retention into the bronchi of bronchial exudate, which is the main cause of hemorespiratory complications and of the dreaded syndrome of bronchial obstruction. On the other hand, as Ameuille, Archibald, Brown and, more recently, Balloon have shown, it promotes the spread of infected mucus into the small bronchi, and the production of "infectious bronchial embolisms," as named by Ameuille.

A number of fundamental problems related to the pathogenesis, and to the mechanics of cough are still unsolved. I shall only mention the uncertainty regarding the contribution of cough to the production of lesions such as spontaneous pneumothorax, of bronchiectasis, and the degree and nature of participation of the diaphragm in cough.

MECHANICS OF COUGH

I believe that a great deal of our discussions on cough are due to our rather confused actual conceptions of the mechanics

* From the Departments of Thoracic Surgery of Sea View and Metropolitan Hospitals of the City of New York, and Department of Surgical Research, Cornell Medical College.

of this complicated phenomenon. In fact, cough is neither a simple aspiratory act nor should it be considered as a whole. It is really composed of three distinct and different phases, which can be described as follows:

First, the inspiratory phase. A deep inspiratory movement in which the chest is dilated by the combined action of the intercostal muscles, the elevators of the ribs, the accessory inspiratory muscles, and the diaphragm. In this phase, the lung is "loaded" with air.

Second, the compressive phase. A short, sudden and powerful expiratory movement during which the *glottis is kept closed*. During this phase a considerable pressure is built up in the lung, which reaches and may exceed 100 mm. of mercury.

Third, the expulsive phase. While the expiratory movement is maintained the glottis is slightly opened, allowing the forceful expulsion of the previously compressed air. A strong draft of air is thus formed which causes the expulsion of foreign matter present in the bronchial tree and irritating the bronchial mucosa.

Thus cough is neither a pure inspiratory nor a pure expiratory act. It is a combination of both, aiming at the expulsion of foreign matter from the bronchi. As such it presents a peculiar likeness with the action of a gun. All three phases of cough are very clearly reproduced in the deflagration of a gun: the loading of the gun, the explosion of the powder and building up of pressure, and finally the expulsion of the bullet. Comparison with a compressed air gun is even more striking.

The importance of this division of cough into three phases becomes readily apparent when we study the physiological characteristics of each.

The Inspiratory Phase.—During the inspiratory phase, the chest dilates and the diaphragm contracts and moves downward. Therefore, the intrapleural pressures become strongly negative. It should be pointed out, however, that this increase in the negative value of the intrapleural pressures is equal in both pleural cavities only if the two lungs are healthy, or dis-

cause in dealing with cough we seldom deal with perfectly normal lungs, and it would be fundamentally wrong to forget the pathologic physiology of the diseased lung.

When the chest dilates, the lung is forced to expand, air rushes into it, the lung inflates and this inflation neutralizes a part of the negative intrapleural pressure by filling the enlarged chest cavity. But the rapidity and completeness with which the expansion of the lung takes place depends upon several factors. The first is that of patency of the upper respiratory ways—larynx, trachea and large bronchi. When, for example an obstacle is present in a common bronchus, the corresponding lung cannot expand, the increased capacity of the chest cannot be filled, and consequently the intrapleural pressure in that hemithorax presents a very considerable decrease, that is, it becomes more negative than in the healthy side. Another cause leading to the same effect is consolidation of the lung. Again, the lack of expansion of the lung, or increased resistance to its expansion, will cause a greater negative pressure during inspiratory enlargement of the chest. After all, it should not be forgotten that negative intrapleural pressure is due to and measures the elastic recoil of the corresponding lung. The results of this abnormal increase of the negative value of intrapleural pressure are numerous. First, in a tuberculous lung, it may facilitate the perforation of superficial subpleural pulmonary caseated areas and, consequently, the production of spontaneous pneumothorax. Therefore, it is a therapeutic necessity to moderate cough in advanced cases of pulmonary tuberculosis. This is even more imperative following intrapleural pneumonolysis, especially when extensive dissections of the adherent lungs were carried out, particularly in cases with bilateral pulmonary tuberculosis.

A corollary of bronchial stenosis, of bronchiolar and alveolar atelectatic consolidation or even of paralysis of the diaphragm is the considerable decrease of the amount of air which can be loaded during this phase into the lung behind foreign matter present in the bronchi. Thus, during the compressive phase very little compression can be built behind the

foreign bodies to be expelled. Hence little or no expulsion will take place in the expulsive phase. A bullet cannot be propelled through the barrel of a gun unless gun powder explodes behind it. Another corollary of the high negative pressure developed in the diseased side during the inspiratory phase is the deviation of the mediastinum. When the contralateral lung is healthy and can expand readily, the intrapleural pressure in that side is obviously less negative than in the side of the diseased lung which cannot expand. Therefore, the mediastinum is deviated toward the side of the latter with a maximum of bulging—mediastinal hernia—at the end of inspiration. The heart is likewise displaced toward the diseased side, causing, occasionally, torsion of the large vessels with distressing symptoms.

Finally, lack of expansion of the diseased lung restricts the inspiratory enlargement of the corresponding hemithorax, thus diminishing the efficiency of this first phase of cough, or even causing inspiratory retraction of the chest wall, known as paradoxical respiration.

The Compressive Phase.—During the second phase of cough the mechanical and physiological phenomena differ entirely. Sudden contraction of the expiratory muscles, the most important of which are the abdominal muscles, materially decreases the chest capacity. The glottis being closed the lung is greatly compressed, and the intrapleural and intrapulmonary pressures become highly and equally positives: 80 to more than 100 mm. of mercury. Since the alveoli are more compressible than the bronchioli and the bronchi, the latter remain patent because of the pressure exerted into them by the compressed alveolar air. The rupture of caseated spots of the lung or of blebs is, theoretically at least, least likely to occur during the second phase. It is difficult to conceive how even a thin bleb can burst if the pressures exerted upon the two surfaces of its walls are equal. During the compressive phase, because of the closure of the glottis, the pressures are independent of the condition of the lung. They are equal in both lungs not only because of their intercommunication, but also

because of the mechanical conditions under which the pressure into and outside of the lungs is built. Authors who consider cough as a whole surmise that it is represented by this compressive phase alone. Thus, Hedblom refused to admit that cough plays any part in dilatation of the bronchi in bronchiectasis. He said, "During cough pressure is uniformly increased inside and outside of the lung so that no dilatation of the

Fig. 73.—Artificial chest. The keyboards of an accordion were removed and replaced with plate glass (A, G) air-tightly fixed in place. In the middle of the accordion a partition was built (B) composed of a wooden frame covered with a thin elastic sheath of dental rubber. The two legs of a Y glass tube (Tr.) were passed through the upper wall of the accordion on each side of the partition. To each of these branches a rubber glove, the cuff of which was tightly ligated, was affixed by means of a hole that had been made in the tip of the ring finger (A and B, R.L., L.L.). In this device the accordion represents the chest, the capacity of which could be made to increase or decrease by opening or closing the accordion, the elastic partition represents the mediastinum, the gloves take the place of the lungs; the Y tubes portray the trachea and common bronchi. An incomplete ligature was placed in the ring finger of one of the gloves (B, lig.) representing a stenosis of the bronchus

bronchi can occur, however diseased and softened their walls may be." This statement, although correct when applied to the compressive phase of cough alone, is entirely wrong when pertaining to cough in general.

The Expulsive Phase.—The third phase of cough is the most important. To study it minutely, an artificial chest was constructed in my laboratory using an accordion (Fig. 73).

The keyboards were removed and replaced with plate glass, airtightly fixed in place of the keyboards. Then, in the middle of the accordion, a partition was built, composed of a wooden frame covered with a thin elastic sheath of dental rubber. After this, two legs of a Y glass tube, were passed through the upper walls of the accordion, on each side of the partition, and to each a rubber glove, the cuff of which was tightly closed, was affixed by means of a hole that had been made in the tip of the ring finger of the glove. When completed, the device consisted of an accordion representing the chest, the capacity of which could be made to increase or decrease by opening or closing the accordion, an elastic partition representing the mediastinum and a pair of gloves taking the place of the lungs, with the Y tube portraying the common bronchi in its two horizontal branches and the trachea in its vertical branch.

Let us watch, now, the successive phenomena in the expulsive phase of cough, which begins with the opening of the glottis. The air compressed in the lungs rushes out as a strong and sonorous draught, carrying with it foreign matter lodged in the bronchi; intrapulmonary pressure rapidly drops until it equals the atmospheric pressure and expulsion then ceases.

There is no difficulty in understanding the mechanics of this phase when the lungs are healthy and the diaphragm normal. It is different when the lung is diseased or the diaphragm paralyzed.

Let us see what happens in the instance of a lung with collapsed alveoli, and retention of exudate in the corresponding bronchi. Stasis and impaired bronchial drainage mean infection of the bronchi with aerobic organisms in the beginning, and anaerobic later, as the oxygen contained in the exudate is absorbed by the white cells and the aerobes. This combined infection leads to the injury and gradual destruction of the musculo-elastic element of the bronchial walls, and to their replacement by connective tissue. With destruction of the elastic and muscular elements, the tonus of the bronchial walls

decreases and so slight and cylindrical dilatation of the bronchi at the diseased portions is produced. However, the nearby bronchi which are still adequately drained and healthy are narrower than the diseased peripheral bronchi, because of: (1) the integrity of their elasticity and tonus, and (2) their reflex contraction due to irritation exerted on their mucosa by the inflammatory process in their neighborhood. The demarcation between the diseased and healthy areas is sharply made and it appears as a stricture. The descriptions of these changes in the bronchiectatic lung by Cruveilhier (1856), Charcot (1881), Marfan (1901), and by other pathologists are classic.

During the first, or inspiratory, phase of cough, the healthy and diseased bronchi are filled with air as a result of the length of this phase and the inspiratory expansion of the bronchial tree. During the second, or compressive phase nothing happens for, as explained above, the pressures inside and outside of the bronchi are equal; but, during the third, or expulsive, phase of cough the mechanism of egress of air from the healthy and from the diseased bronchi are radically different. In fact, air rushes out of the healthy bronchi easily, since their diameter increases toward the lobar bronchus and there is, therefore, little resistance to the expelled air, the pressure falling very rapidly to the level of atmospheric pressure. In the diseased areas, on the contrary, the narrowings above the enlarged bronchi offer a considerable resistance to the egress of air. Thus, at the time that the pressure in the healthy parts of the lung has already reached the atmospheric level, it is still above that level in the diseased bronchi. In other words, during the expulsive phase of cough pressures are higher into the diseased than in the healthy bronchi. Obviously this difference of pressures must cause a gradual and progressive dilatation of the diseased bronchi. This is not theorizing because it is by the same well-known mechanism that obstructive emphysema is produced. In bronchiectasis, instead of dilatation of the alveoli as in emphysema, dilatation of the bronchi takes place: in fact, when the alveoli have undergone inflammatory

organization and definite closure following plastic alveolitis or pulmonary sclerosis or organized atelectasis, which can be caused by any pulmonary lesion, chronic retention of bronchial exudate is established in the bronchi. Bronchial stasis takes place in these test tube-like bronchi because the absence of air distally brings about suppression of the expulsive phase of cough which represents the most efficient mechanism of bronchial drainage.

This is not all, however.

Owing to the narrowing of the bronchial lumina above the diseased bronchi, the air is not completely expelled at the end of the expulsive phase of cough. Thus, the beginning of the next inspiration finds the diseased areas still air-containing so that the discrepancy in pressure during the expulsive phase between healthy and diseased bronchi is still further increased. This mechanism of production of bronchial dilatation or obstructive emphysema was clearly demonstrated with the artificial chest. When an incomplete ligature was placed on the finger connecting one of the gloves to the Y tube (Fig. 73, B, lig.) to produce narrowing of the finger, it was found that after opening and closing the accordion in imitation of a number of strong inspiratory and expiratory movements, if the motion was halted in expiration the glove representing the diseased lung remained expanded, due to the narrowing of the finger, whereas the other glove collapsed. This has furnished additional proof in support of my contention that, contrary to prevailing opinion, bronchial dilatation in bronchiectasis is due to cough.

ACTION OF THE DIAPHRAGM IN COUGH

The function of this musculo-aponeurotic membrane in cough has acquired considerable importance since the widespread practice of phrenic nerve interruption in the treatment of pulmonary tuberculosis. In reviewing the literature, we find the most contradictory statements. Many sponsors of paralysis of the diaphragm in the surgical treatment of pulmonary tuberculosis claim that by this method "expectoration is increased and rendered easier." Others, however,

maintain that expectoration decreases and that diaphragmatic paralysis favors the development of bronchial retention and obstruction. Still another group report no sizable changes. What are the real results of interruption of the phrenic nerve? What is the rôle of the diaphragm in the phenomenon of cough?

A priori, there should be none. The diaphragm being an exclusively inspiratory muscle should have nothing to do with cough, if cough is regarded solely as an expiratory phenomenon. The inability of physiologists and clinicians to offer a definite solution to this problem was evidenced in an editorial on cough in the J.A.M.A. in 1928 (xci, 1894) in which there appeared this statement: "In all acts of expulsion, sneezing, coughing, laughing, vomiting, and crying, the diaphragm adds force to the expulsion efforts." Surprised by this statement, Dr. W. D. Toethout addressed a letter to the editor (xcii, 496, 1929) as follows: "Kindly explain how the contraction of the diaphragm can contribute to expiratory efforts." The editor (xcii, 496) in his answer corrected his previous statement and acknowledged: "There is at present no evidence that the diaphragm adds power to these processes (sneezing, coughing, laughing and crying which are expiratory acts) and of favoring the expulsion of air from the lungs."

Should we then conclude that the diaphragm is of no importance in the act of cough?

Certainly no one will deny that contraction of the diaphragm produces a powerful compression of the abdominal viscera; thus, when the diaphragm and the abdominal muscles contract simultaneously the diaphragm concurs to the increase of intra-abdominal pressure and to the expulsion of the contents of the abdominal viscera either through the mouth (retching, vomiting), or through the rectum (defecation), or through the urethra (urination). In these phenomena, however, it is to be noted that the diaphragm acts as an abdominal and not as a thoracic muscle. Its action is two-fold: direct, *i. e.*, pressure upon the viscera. and indirect, *i. c.*, immobilization of the chest upon inspiration with a closed glottis, so that there is

furnished a solid, unyielding upper insertion to the abdominal muscles, especially to the recti and the obliques.

But when the diaphragm is functioning as a thoracic muscle, its action is totally different.

During the *inspiratory phase* of cough, or of laughing, sneezing, crying, or singing, the participation of the diaphragm is obvious; it is an essential factor in loading the lungs with air. When it is paralyzed, there is less marked inspiratory enlargement of the corresponding hemithorax and lung and less than normal amounts of air are drawn into the lung; the immobility or even the rise of the paralyzed diaphragm during inspiration does not produce the necessary increase of the vertical diameter of the hemithorax. This deficiency is more marked in patients with thoracoplasty in which costal motion is suppressed.

It is my contention that the action of the diaphragm is equally important during the second, or *compressive phase* of cough. It is obvious that positive pressure in the chest cannot be produced unless its walls have become rigid and unyielding. Immobilization of the ribs by the contraction of the expiratory muscles insures such rigidity. But since the floor of the chest cavity is represented by the diaphragm, so long as this part of the chest is not rigid no high positive pressure can be attained in the chest. This can only be accomplished by the simultaneous contraction of the diaphragm and of the abdominal muscles.* Only by the push of the abdominal viscera against the contracted diaphragm can this rigidity of the floor of the chest be insured. Therefore, we must conclude that in the compressive phase of cough the diaphragm acts as an antagonist to the abdominal muscles; and, since the principal expiratory muscles are the abdominal muscles, we must admit that, apparently at least, *not only the diaphragm does not help cough, but, on the contrary, it opposes it by restraining the elevation of the abdominal viscera*. It seems, therefore, that the

* It may be a matter of discussion whether a real contraction of the diaphragm takes place or the tonus (or status) of this musculo-aponeurotic membrane suffices to insure the rigidity of the floor of the chest. This question will be taken up in a forthcoming paper.

expulsive action of cough is under the control of two antagonistic muscular systems: of the diaphragm and the abdominal muscles. So far as I know, this concept of the action of the diaphragm has not been presented hitherto. It is, however, of great significance because, if I am right, it explains the mechanism of the refined regulation of the expulsive action of cough. In fact, all movements in the organism, skeletal or visceral, are dependent upon two antagonistic muscular systems. By means of the fine interplay of these antagonistic systems acting synergistically, with one acting as a brake upon the other, movements are regulated to a smooth course with a minimum loss of time and energy and a maximum of accuracy.

In the third, or *expulsive*, phase of cough, this action becomes more apparent. If we inspect the abdomen of a man during cough, we see that in each coughing effort a movement of retraction of the abdominal wall takes place. When a subject is instructed to perform successive movements of cough without inspiratory interruption, we see successive contractions of the abdominal wall so that it retracts each time a little more than in the preceding movement. When the subject is examined fluoroscopically under the same conditions, the diaphragm is seen to assume a more elevated position with each cough. It does not permit the abdominal viscera to jump upwards into the chest cavity as occurs when the diaphragm is paralyzed; the intact diaphragm opposes, limits and regulates the visceral push. This is particularly noticeable when a subject makes successive movements of cough in an endeavor to expel tenacious sputum; in each movement of the cough the diaphragm rises a little more, thus preventing the waste of air enclosed in the lungs and making the best use of it. In other words, the synergic action of these two antagonistic muscular systems regulates the action of cough and adjusts its expulsive strength to the resistance offered by foreign bodies lodged in the bronchi.

I believe, in short, that it is unwarranted to accept that the diaphragm "helps cough" or "opposes it" or "has nothing to do with cough." The rôle of the diaphragm in cough is a

different one. It is a "coordinator of cough," insuring the fine adjustments of cough by regulating its action and strength to the resistance to be overcome.

EXPERIMENTAL DATA

Experimental and clinical studies of animals and patients with a paralyzed diaphragm have corroborated this conclusion.

Experimental investigations upon changes in cough after phrenicectomy in dogs have recently been carried out by Carlsen, Balloon, Wilson and Graham, Kinsella, and more recently by Fine and Starr. Graham and his collaborators found that the efficiency of cough is decreased after phrenicectomy, as shown by retarded elimination of lipiodol in the side of the paralyzed diaphragm. Kinsella has found this to be true, also, in the human. Fine and Starr conceived the idea of performing bilateral phrenicectomy on dogs in order to eliminate any possible error due to contraction of the contralateral diaphragm. After graphs were taken by these authors on the normal animal, both phrenic nerves were cut by pulling on wires that had been previously placed around them. No change in the height of the expiratory blasts could be noted and so Fine and Starr concluded that "paralysis of the diaphragm affords neither help nor hindrance to the force of the expiratory blast. . . . If cough is somewhat less efficient it must be related to other factors such as reduced expansion of the lungs with consequent decrease in the air available for the expiratory blast."

These experiments, however, convey only a rough idea of what happens in cough. They register the final results of phrenicectomy upon the strength of the expiratory blasts, but do not furnish information regarding the finer changes of intrapleural and intrapulmonary pressures during the different phases of cough in patients with or without a paralyzed diaphragm.

Therefore, we have deemed it of interest to conduct a number of experiments upon patients with a pneumothorax and having an intact or a paralyzed diaphragm.

We conjectured that, since changes of intrapulmonary pres-

sure are due to, and caused by, changes in the capacity of the chest cavity, measurement of intrapleural pressures might supply accurate information as to what happens during cough. On the other hand, recording the changes of intrapleural pressures during cough in the human would eliminate a number of errors likely to occur in experiments on animals, especially the dog. In fact, in animals the cough should be produced by artificial stimulation after anesthetizing the animal; in the dog the flexible mediastinum cannot be likened to the more resistant human mediastinum.

Two of the patients in whom the experiment was carried out had the following histories:

Case I.—T. G., twenty-three, female Puerto Rican, bilateral pulmonary tuberculosis: had had bilateral pneumothorax, completed by bilateral pneumonolysis. Both upper lobes were selectively collapsed while the lower lobes of both lungs were allowed to reexpand. The vital capacity was 1200 cc. The phrenic nerves were intact and the function of the diaphragm was normal. Ambulatory case.

Case II.—F. L., twenty-two, female, white, had a pneumothorax in one side. A complete avulsion of the phrenic nerve (30 cm.) had been performed previously. Pneumonolysis was performed for section of apical adhesions which had opposed a selective collapse of the apex. Actually the upper lobe was selectively collapsed while the lower lobe was allowed to reexpand. Vital capacity 1400 cc. Ambulatory case.

The two cases were as similar as could be, with one exception: the diaphragm of Case II was paralyzed.

Technic.—A needle was introduced into the pleural cavity of each patient and tracings were taken by means of a chloroform recording manometer on a revolving smoked drum. In Case II, the needle was introduced into the side corresponding to the paralyzed diaphragm.

The patients were instructed to cough twice in succession and without inspiratory interruption so that each curve on the graph would represent two movements of cough without an intervening inspiration.

The tracing of Case I (normal diaphragm) is represented in Fig. 74. A few quiet respiratory movements were recorded (inspiration appearing in downstrokes) before the subject

Fig. 74.—Graph of cough of a patient with pneumothorax and normal diaphragm. See details in the text

Fig. 75.—Graph of cough of a patient with pneumothorax and paralyzed diaphragm by previous phrenicectomy. See details in the text

coughed. Analyzing the graph, $a-a'$ represents the deep inspiration preceding cough (inspiratory phase); $a'-b$, the compressive and expulsive phases of the first cough; $b-c$ the same phases of the second cough; and $e-e'$ and $e'-f-g-h$ repetitions of the same movements.

In Fig. 75 the record of Case II is shown. $a-a'$ again represents the inspiration preceding cough; $a'-b$ the first cough; and $b'-c$ the second cough. The remaining two tracings repeat the phenomenon.

In both tracings, $a-a'$ represents the first inspiratory phase; $a'-b$ and $b-c$ the second, or compressive phase, and $c-d$ the end of the expulsive phase. All other conditions being alike in both cases, it is reasonable to conclude that whatever the differences, if any, in the two tracings, they must be attributable to the paralysis of the diaphragm in Case II.

In Case I the inspiratory phase is represented by a clean-cut vertical line, $a-a'$. In Case II this line $a-a'$ is interrupted and less vertical. Obviously, therefore, inspiration was less efficient in Case II due to paralysis of the diaphragm.

In the second phase of cough, there are more interesting variations in the two tracings. In Fig. 74 a continuous effort is apparent, the expiratory strength being maintained throughout the duration of the two cough movements. Although there is a slight arrest in b and f , indicating the end of the first cough and the commencement of the second, there is no drop in pressure. In Fig. 75, however, we find that a marked drop in the intrapleural pressure occurred between the two coughs, represented by line $b-b'$.

Interpreting these experimental data, we find that in Case I, with an intact diaphragm, the upward push of the abdominal viscera, caused by the contraction of the abdominal muscles, was checked by the contracting diaphragm so that, between the first and second acts of cough, there was no drop in intrapleural pressure and none, consequently, in intrapulmonary pressure. Line $b-c$ represents a continuation of line $a'-b$; as does $f-g$ of $e'-f$. On the contrary in Case II with a paralyzed diaphragm, the intrapleural, and consequently the intrapul-

monary pressures, dropped between the first ($a'-b$) and the second ($b'-c'$) movements of cough, due, I believe, to an absence of contraction of the diaphragm which permitted the abdominal viscera to jump upward unchecked, obedient to their inertia. When the push of the abdominal muscles was slightly and momentarily relaxed between the first ($a'-b'$) and second coughs ($b'-c$), the viscera, obedient to gravity, fell back ($b-b'$), indicating a loss of energy. The result of this waste is shown in the decrease of the total height of the line $a'-b-c$ of Fig. 75 compared to the height of the same line, $a'-b-c$, of Fig. 74. This waste of energy is even more considerable than is apparent in view of the fact that Case II had a greater vital capacity than Case I. Obviously, then, the diaphragm (an inspiratory muscle), by its cooperation with the abdominal muscles (expiratory muscles) in the regulation cough, the prevention of a waste of energy and the adjustment of its strength to the need, represents a vital factor in the efficiency of cough.

SUMMARY

Four new concepts are offered:

1. Cough is shown to be a complex phenomenon having three well-defined phases: inspiratory, compressive and expulsive. The mechanics and physiology of each phase are described.
2. The action of cough in the production of bronchiectasis is presented.
3. The action of the diaphragm in cough is studied. Clinical and experimental evidence is presented leading to a new conception of its action.
4. The diaphragm does neither help nor hinder the action of cough. It acts as a regulator of cough and adjusts its action to the resistance offered by foreign bodies lodged in the bronchi.

CLINIC OF DR. MILTON A. BRIDGES

SEA VIEW HOSPITAL

DIET PRESCRIPTION FOR THE TUBERCULOUS*

DIET plays an important rôle in both pulmonary and extrapulmonary tuberculosis. Irrespective of the psychologic import of gained weight with its euphoric acceptance by both the patient and the physician, a better understanding of the nutritional demands of the tuberculous does not always sanction this physical gain.

At this writing, pulmonary tuberculosis is evaluated, not by the extent of the disease, but by the character of the infection. The acute exudative forms present a sudden and toxic beginning. When this is associated with pulmonary necrosis, caseation and liquefaction promptly follow. The necrotic tissue is expectorated with resultant cavity formation. From the start of this type of tuberculosis, the victim is prone to be intensely toxic. With the expectoration of necrotic lung tissue, the symptoms of toxemia begin to disappear. Unfortunately, the resultant cavitation being an excellent culture medium for the tubercle bacilli, the bacteria multiply rapidly. This commonly results in further pulmonary involvement with recurrent toxemia.

Hence, the clinical picture of pulmonary tuberculosis is a variegated one as can be readily seen, requiring frequent dietary changes. Most difficulties are encountered during the febrile periods.

The dietetic care of febrile conditions has been universally divided into two types, one for fevers of short duration, such

* The food listings and menus in this article have been taken from Bridges' "Dietetics for the Clinician," Lea & Febiger, Philadelphia, Pa.

as are encountered in influenza, la grippe, tonsillitis, etc. In these conditions the diet proves to be essentially one of starvation. Solid foods are prohibited and a high fluid intake with moderate carbohydrates, no fats and low in caloric value is instituted. This temporary starvation unassociated with acidosis proves beneficial and is felt to hasten convalescence.

The second type of dietetic care of the pyretic is directed at fevers of longer duration in which category tuberculosis probably is the most common.

Great credit should be extended to Coleman and Shaffer, who in 1907 presented to the medical profession a revolutionary diet for typhoid fever. Prior to their presentation the dietetic care of the typhoid was one of pseudostarvation for the duration of the disease, with the result that very commonly the period of convalescence exceeded by far, the time occupied by the acute course of the malady. The older interdiction of food was due to the always present fear of producing perforation or hemorrhage. As a result of this negative diet convalescence was occupied in restoring to normal, a markedly underweight, starved and anemic individual.

In the absence of knowledge of liver therapy, vitamins and the proper administration of hematics, as was the case several decades ago, it can be readily understood that the time consumed in accomplishing this desired restoration was tedious and often fruitless.

Those interested in nutrition have definitely reached the conclusion that poundage is not the *sine qua non* of health. The older school emphasized the continued gain of weight of the tuberculous patient. This they accomplished by what is now evident to be a shotgun overfeeding. Those whose work has been restricted to tuberculosis have seen the falsity of this trend of thought.

At the present writing, it has as yet been undetermined what rôle diet plays in establishing the resistance of the individual to tuberculosis. It is well recognized, however, that undernourishment predisposes to a questionable prognosis. Clinical experience has taught that a moderately high caloric

diet, well-balanced in minerals and vitamins offers a patient a more favorable outlook.

A review of the literature in reference to man's energetic requirements reveals many discrepancies. These variations in opinion are due to the inconsistency of recognition on the part of various observers, of the many factors which influence such requirements.

Age, sex, weight, height, size (surface area), muscular activity, body temperature, brain activity, together with climatic and other environmental conditions so alter requirements that it can readily be seen that no one formula can be applied to the feeding of the human mechanism in health or disease.

In spite of the presence of all these variables, some standard must be established in order to intelligently feed the sick. The consensus of opinion as to food requirements expressed in the amounts of carbohydrates, proteins and fats required by the average person (150 pounds) per diem, is: carbohydrates, 350 Gm.; proteins, 100 Gm., and fats, 150 Gm., totaling about 3200 Calories. This energetic requirement is estimated as being necessary for the average working man. Each of these components has been the subject of much divergence of opinion.

Recently an analysis of large groups of non-dieting individuals in a cosmopolitan city, revealed that the total protein intake per diem was closer to 50 than to 100 Gm. In urban life, the ingestion of 150 Gm. of fats seems reasonable. The inclusion of 350 Gm. of carbohydrates in the daily dietary of the average individual is subject to marked variation, due principally to occupational pursuits.

It is generally believed that the adult requires from 10 to 35 Calories per pound of body weight in direct relationship to an activity varying from resting to heavy physical exertion. In gross Calories calculated on the basis of 150 pounds, this means 1500 to 5200 Calories daily.

It has been well established that the presence of fever increases the body metabolism to an extent which requires greater caloric intake to offset the burning of endogenous nu-

tritive material. Hence, the total caloric intake demands an increase over the normal calculated maintenance level when fever is present. This is especially true in relation to the protein allotment.

The average daily mineral requirement is also subject to much controversy which in turn is based upon the question of availability and assimilation of the various minerals. The accepted guide for the daily requirement is considered to be: calcium, 10 mg.; phosphorus, 15 mg.; iron, 0.2 mg.; and magnesium, 0.3 mg.; per kilogram of body weight. A well-balanced diet fully meets these demands.

Coincident with the marked advances in physiology, biochemistry as well as mineral chemistry, feeding of the sick has departed markedly from the old axiom of just "feeding" to "prescription feeding." The author feels that the great amount of research which has been devoted to the study of diabetes and its associated problems has done more to enlighten the profession in reference to feeding of the physical being in both sickness and health, than any other factor in the study of disease. Recently, advances made in the dietetic care of gallbladder diseases again reveal a better understanding and evaluation of the relationships of food chemistry and physiology in conjunction with a newer understanding of the pathologic entities in the gastro-intestinal tract. As a result, the prescription of a diet for diabetes or the diseased gallbladder is no longer a ready-made coat to cover anybody, but a well-tailored garment fitted to the individual figure.

The proper approach to the dietetic care of the tuberculous patient is to initially establish a complete inventory of the physical being for whom a diet is to be prescribed. This comprises a complete chemical blood study with particular reference to blood calcium, urea nitrogen, nonprotein nitrogen, sugar, uric acid, chlorides, phosphorus and hemoglobin. An estimation of the presenting weight in relation to the calculated weight establishes an objective which should not be lost sight of.

Additionally, in order to avoid unpalatability and food aversion, cognizance must be taken of the past dietary habits and any existing intolerance or allergic reaction determined.

Another factor so often overlooked, is the lack of regard for the commonly associated anorexia. When the appetite is small it is ridiculous to outline large volumetric meals. This obstacle can frequently be met most simply by omitting all non-caloric bearing liquids, hence reducing the meals to items with high caloric yield.

It has generally been accepted that an overabundance of vitamins B, C and D are indicated. For ready reference the appended listing presents in concrete form the latest classification under these respective vitamins:

Vitamin B ₁	Vitamin C	Vitamin D
Dried brewer's yeast*	Citrus fruits*	Fish liver oils*
Wheat germ*	Parsley*	
	Peppers, green or red*	Burbot (European)
Avocado	Raw new cabbage*	Butter (variable)
Bread, whole wheat	Tomato juice*	Clams
Cabbage, raw	Watercress*	Cream
Carrots		Egg yolk
Fruits in general	Cranberries	Haddock
Leafy vegetables	Cucumbers	Halibut
Legumes	Fresh fruits	Herring
Nuts	Fresh, raw vegetables	Oysters
Okra	Pimentos	Salmon
Oysters	Potatoes	Sardines
Peppers	Tomatoes	
Pork		
Rice, brown		
Spinach		
Tomatoes		
Wheat bran		
Whole cereal grains		

The question of calcium administration should be based upon the blood calcium determination. However, the administration of foods high in calcium whether indicated by blood analyses or not has never been proved detrimental. The fol-

* Outstanding

Following list presents a classing of foods which have been determined as containing the higher amounts of calcium:

FOODS HIGHEST IN CALCIUM

In order of decreasing percentage.

Skim milk powder	Kale	Wheat bran
Cheese, rennet	Caviar	Citron
Whole milk powder	Figs, dried	Cocoa, dry
Mustard	Navy beans, dried	Clams
Jelatin, dry	Watercress	Oats, entire
Turnip greens	Ice cream	Maple syrup
Malted milk	Whitefish	Cabbage greens
Condensed milk	Kidney beans, dried	Buttermilk
Filberts	Egg yolk	Endive
Evaporated milk	Boston brown bread	Lentils, dried
Molasses	Broccoli	Horseradish
Almonds	Cauliflower	Olives
Collards	Capers	Shrimp
	Whole and skim milk	

Even though phosphorus metabolism is intimately associated with that of calcium it might be well to list those foods highest in phosphorus:

FOODS HIGHEST IN PHOSPHORUS

In order of decreasing percentage.*

Wheat bran	Oatmeal	Corned beef
Meat peptone	Chocolate, sweet	Brown rice
Wheat germ	Peas, dried	Rye flour
Skim milk powder	Barley, entire	Veal roast
Swiss cheese	Peanuts	Codfish, salt
Mustard	Rye, entire	Tuna fish, canned
Cocoa, dry	Lentils, dried	Salmon, smoked
Cheddar cheese	Beef brain	Mackerel
Whole milk powder	Corn, dried	Quail
Egg yolk	Wheat, entire	Chicken, lean
Yeast	Turkey, light meat	Ham, fresh, lean
Navy beans, dried	Walnuts, English	Sardines
Cashew nuts	Filberts	Malted milk
Kidney beans, dried	Breakfast wheat	Whitefish
Almonds	Lima beans, dried	Cottage cheese
Chocolate, bitter	Pecans	Salmon, canned
Turkey, dark meat	Pot cheese	Whole wheat bread
	Beef, dried	

* These items contain over 250 mg. per cent.

Subnormal blood nitrogen readings are pathognomonic of insufficient protein ingestion. Aside from the chemical blood findings the presence of fever always necessitates a higher protein intake than normal. For convenience appended is a list of those foods highest in proteins:

FOODS HIGHEST IN PROTEINS

Almonds	Fish	Pine nuts
Butternuts	Fish roe	Pistachio nuts
Cashew nuts	Gelatin, dry	Poultry
Cheese	Gluten products	Protein milk
Crustaceans	Legumes, dried	Soy bean products
Eels	Meats, lean	Walnuts, black
Egg	Milk powders	Wheat cereals
	Peanuts	

In the presence of anemia, either nutritional or due to hemorrhage, it is indicated to administer those foods most capable of increasing hemoglobin. Fortunately, the dietetic care of pernicious anemia has resolved the blood-building chaos into a specific dietary prescription. The necessity of sufficient vitamin A in the correction of anemia has been widely stressed. A predominance of this vitamin is found in the following foods: butter, fish liver oils, tomato, egg yolk, milk and leafy vegetables, principally cabbage, cauliflower, lettuce and spinach. The effect of the ingestion of iron, as obtained from foods, is thought to be synergistically enhanced by the associated presence of copper and manganese. The following foods carry the highest combination of these three minerals:

Almonds	Cocoa, dry	Pineapple
Beans, kidney	Filberts	Pistachio nuts
Beans, lima	Lentils	Spinach
Beef juice	Liver, calves'	Walnuts
Cherries, fresh	Olives, green	Watercress
Chocolate, dry	Parsley	Wheat bran

Those foods containing the highest amount of iron, irrespective of their manganese or copper content, are herewith presented:

FOODS HIGHEST IN IRON

In order of decreasing percentage.*

Blood	Walnuts, black	Quail
Beef juice	Beef kidney	Chicken, lean
Parsley	Calves' liver	Oatmeal
Apple butter	Dates	Corn
Wheat bran	Beef heart	Veal roast
Beef liver	Currants, dried	Barley, cooked
Molasses	Breakfast wheat	Turnip greens
Pistachio nuts	Filberts	Sauerkraut
Egg yolk	Seedless raisins	Oysters
Sweetbreads	Chestnuts	Mushrooms
Watercress	Lean beef	Squab
Seeded raisins	Almonds	Mincemeat
Butternuts	Spinach	Chocolate, bitter
Apricots, dry	Figs, dry	Cocoa, dry
Avocado	Brazil nuts	Maple syrup
Dried beef	Pickles, sweet	Bacon, crisp
Dandelion greens	Prunes, dried	Boston brown bread

The following foods have been proved to be highest in *hematopoietic power*:

Apples	Bone marrow	Lettuce
Apricots	Brains	Peaches
Asparagus	Calves' liver	Pig kidney
Beef heart	Chicken gizzard	Pineapple
Beef kidney	Chicken liver	Prunes
Beef liver	Fish liver	Raisins
Beef spleen	Lamb kidney	Strawberries
	Lamb liver	

The question of dehydration which both medically and surgically has been a *bête noir* to the profession, can be viewed with much less alarm when its chemistry is better understood. Bearing in mind that this condition exists only in the absence of sufficient osmotic tissue tension, it is imperative that this be altered to restore the proper tissue balance. In cases of inordinate tissue retention, *i. e.*, cardiac failure with edema, hepatic cirrhosis, Addison's disease, various types of nephritis, etc., all are in accord as to salt restriction. In dehydration the opposite view should be instituted and salt should be liberally administered.

It is only of recent years that the profession has come to recognize that the offending radical in salt is not that of

* These items contain over 3 mg per cent.

chlorine but of sodium. An illustration admirably bearing this out is ammonium chloride which is recognized as being an efficient diuretic, whereas sodium bicarbonate in excessive quantities will produce a generalized edema.

A further illustration of the prompt results produced by the overingestion of salt was observed by the author in the course of gastric tube feedings in a case of anorexia nervosa. Four feedings were given daily through a duodenal tube. During the first series of treatments 1 level teaspoonful of table salt was given with each feeding with no untoward results. At a subsequent period of treatment, approximately a year later, the salt administered was inadvertently increased to a heaping teaspoonful per feeding. The clinical response was to increase the body weight 16 pounds in six days with associated physical distress. This was exhibited by severe multiple joint pains and a general water-logging of the entire body. By way of interest we happened to have control blood chlorides and as soon as the presenting symptom was suspected, a redetermination of the blood chlorides showed a marked increase.

The majority of the salt substitutes, which unfortunately have been recommended to and used by the profession, are no better than sodium chloride itself. These carry the full complement of sodium bound with some other base. Some others present a combination of both sodium and potassium which naturally reduces the total sodium intake to some degree but does not obviate the obnoxious sodium radical.

The following list presents those foods which analytically have been found to be highest in sodium in contradistinction to sodium chlorides:

FOODS HIGHEST IN SODIUM

Bread	Egg white	Paprika
Butter	Endive	Pepper, black
Carrots	Lima beans, dry	Raisins
Caviar	Meat extract	Spinach
Cheese	Olives	Watercress
Clams	Oysters	Wheat bran
Crackers (biscuits)		Wheat germ

All brined, corned, pickled, smoked and salted foods.

It must not be overlooked that whereas the average tuberculous patient at the time of diagnosis is generally underweight, it cannot be concluded that this is the case in all patients presenting this disease. It is well recognized that pulmonary tuberculosis afflicts the overweight in a surprisingly large number. In these instances a high caloric diet naturally is not to be observed. The caloric yield should be reduced but the protein factor should be maintained at the proposed high level.

Tuberculous enteritis is a common complication of pulmonary tuberculosis. Strangely, this is especially true in those cases with cavities. Some authorities believe that every cavity case with positive sputum should be looked upon as a potential tuberculosis of the intestines. In such conditions a non-residue diet is advised. This necessarily limits the administration of leafy and root vegetables and fruits which in turn almost eliminate the presence of vitamin B. Inasmuch as this deficiency affects chiefly the gastro-intestinal tract and the nervous system, it is recommended that a vitamin B concentrate be added to the diet. In a similar manner some workers believe that both vitamins C and D have a selected favorable effect on intestinal tuberculosis. This view indicates the addition of both cod liver oil and tomato juice.

It is not uncommon to encounter an associated disturbance of calcium metabolism in tuberculous enteritis or colitis, which has been observed to result in tetany or tetanoid symptoms. This necessitates specifically infiltrating into the diet, those items high in calcium which are not contraindicated due to their roughage content. Foods most readily adaptable are milk in any form and egg yolk.

In *pulmonary hemorrhage* all food and fluids should be stopped for twelve hours. During this period small pieces of ice may be given to allay thirst. After the twelve-hour period a typhoid fever type of diet should be instituted. This diet is high in caloric value, soft and high in fluids. When temperature and hemorrhage have ceased, return to the regular diet as indicated.

In *tuberculosis of the larynx* with dysphagia, the regular diet for tuberculosis as hereafter outlined, is recommended.

In tuberculosis of the larynx with dysphagia, it is necessary to plan menus which are not bulky and are bland, so that increased salivation and pain can be somewhat controlled. In severe cases the nutrition is maintained with considerable difficulty. The type of diet for this condition varies directly with the degree of dysphagia present. In brief, the diet resolves itself into one which is either fluid or semifluid in character. A practical rule to follow is that all foods which "pour" should be administered.

In résumé, the regular diet for pulmonary tuberculosis should be high caloric, high protein, to which has been added a liberal supply of all vitamins with particular emphasis on vitamins B, C and D. Additional augmentations or deprivations will depend upon the individual demands of the case at hand.

Needless to say the writer does not believe that dietary care of the tuberculous is the *sine qua non* of recovery. In the presence of the moot question of availability and assimilation of the nutritive as well as mineral content of foods, it would be foolhardy to rest upon diet alone for optimum response. The selection of proper climate, bed rest, passive and active exercise, together with corrective as well as alleviative medications in conjunction with a proper diet should produce a *tout ensemble* capable of complete restoration to health.

In conclusion, the following sample menus epitomized from the preceding material can readily be instituted for the average tuberculous sufferer.

Advised

<i>Meats</i>	<i>Dairy products</i>	<i>Fish</i>	
Beef	Butter	Bluefish	Oysters
Lamb	Cheese	Clams	Shrimp
Liver	Cream	Cod	Salmon
Mutton	Eggs	Flounder	Trout
Poultry	Eggwhite	Halibut	Tuna
		Mackerel	Weakfish

Alimentary Pastes

Bread	Pastry
Cake	Pie
Cereals	Rolls
(cooked)	
Cereals (raw)	

Vegetables

Beans	Peas
Carrots	Potatoes
Celery	Spinach
Lettuce	Turnips
	Tomatoes

Fruits of all characters, both fresh and stewed, should be freely utilized.

Reasonable care should be exercised in the use of the following, although their use in moderation is not actually prohibited: tea and coffee, beer, ale, in tonic doses; pork products other than bacon and smoked ham.

SAMPLE MENU No. 1

Breakfast:

Orange juice (chilled)
Oatmeal or hominy with cream and sugar
Poached eggs on toast
Two slices of fatty bacon
Buttered toast
Marmalade
Hot chocolate

Mid-morning:

Milk with bread and butter

Dinner:

Beef broth with rice or noodles
Broiled liver and bacon
Creamed potatoes
Buttered carrots
Tomato salad with mayonnaise dressing
Rolls and butter
Lemon meringue pie or fruit pie
Milk or half milk and cream

Mid-afternoon:

Eggnog with additional white of egg

Supper:

Cream of corn soup
Vegetable plate
Bread and butter
Cup custard
Milk or junket

Bedtime:

Hot malted milk and nuts

SAMPLE MENU No. 2

Breakfast:

Chilled melon or grapefruit juice
Cream of wheat or Pettyjohn's with cream and sugar
Two soft boiled eggs
Two slices of fatty bacon
Buttered toast with jelly
Hot cocoa

Mid-morning:

Milk with toast and butter

Dinner:

Chicken broth with noodles or rice
Roast beef
Baked potato with butter
Creamed cabbage or cauliflower
Pineapple and cottage cheese salad, French dressing
Hot tea biscuits and butter
Tapioca pudding and cream
Milk or half milk and half cream

Mid-afternoon:

Eggnog with additional white of egg

Supper:

Cream of mushroom soup
Broiled fish with butter sauce
Buttered spinach
Blanc-mange with cream
Ovaltine

Bedtime:

Hot malted milk with white of egg and dates

SAMPLE MENU No. 3

Breakfast:

Glass of grape juice or berries with sugar and cream
Farina with cream and sugar
Two eggs scrambled in milk
Two slices of fatty bacon
Buttered toast and jelly
Hot cocoa

Mid-morning:

Malted milk (flavored)

Dinner:

Cream of asparagus soup
Leg of lamb, mint jelly or sauce
Fresh green peas or lima beans in butter
Candied sweet potatoes

Avocado salad with French dressing
Rolls and butter
Ice cream and plain cake
Hot cocoa

Mid-afternoon:

Eggnog with butter cookies

Supper:

Cream of tomato soup, whipped cream
Minced chicken on toast
Graham muffins and butter
Fruit cup
Milk or half milk and half cream

Bedtime:

Hot malted milk and raisins

The patient should not be allowed to sleep late into the morning. The breakfast hour is 8 A. M. If breakfast is served at 10 A. M. and the extra feeding given an hour later there will be little room in the stomach for more food at noon! Breakfast should be served at 8 A. M., dinner at 12:30 or 1 P. M. and supper at 6:30 P. M. The meals are to be supplemented by feedings at 10 A. M., 4 P. M. and 9 P. M. Warm milk at 9 P. M. may assist in promoting sleep. The addition of eggwhite at all times will prove efficient in increasing the daily protein intake.

When marked underweight is present it often proves efficacious to omit all water and substitute caloric yielding fluids. This is most likely to be proficient when the appetite is small or a genuine anorexia obtains.

CLINIC OF DR. WALTER A. BASTEDO

ST. LUKE'S HOSPITAL

CHRONIC CONSTIPATION

CONSTIPATION is inadequacy of bowel movements, but its effects may be far-reaching, as noted by observant laymen. Henry Ward Beecher used to amaze inquirers at revival meetings by asking them, not questions about their souls or conduct, but did their bowels move regularly. He had observed that penitence was often due to constipation rather than to piety. Josh Billings rated "a good sett of bowells" higher than brains. Voltaire remarked that "A 'No' from one whose bowels move every morning is more gracious than a 'Yes' from one who is constipated."

The symptoms associated with constipation, viz., mental depression, pessimism, headache and physical inefficiency, would seem to be due either to the absorption of toxic substances formed by bacterial action, to the absorption of unchanged proteins (allergy), or to the absorption of attenuated bacteria as postulated by Adami. Of toxic substances any measurable effect is dependent chiefly upon the inability of the liver to destroy them.

The most common putrefactive poisons, skatol, indol and phenol, will produce such toxic effects in healthy men or animals by mouth doses, but only when large amounts are administered: Powers and Sherwin say 50 mg. per kilogram of body weight. In experiments done in my laboratory at Columbia by Howland and Richards and watched closely by me, indol and phenol were administered in increasing doses to dogs, rabbits, guinea-pigs, rats, and mice. The effect of a small

dose was to make the animal mope and keep away from its fellows, a larger dose made it really ill and as if it might have a severe headache, and finally a dose was reached that produced convulsions. But when the detoxifying power of the body, chiefly seated in the liver, was destroyed by minimum doses of cyanide, convulsions ensued more readily, even from an amount one-fifth or one-sixth as large.*

In those with sluggish bowels but not pronounced constipation, the heavy head, forgetfulness and depression may diminish markedly after a free movement of the bowels, and disappear wholly in an hour or two. But the fact that this relief does not follow if the movement is of constipated type, and, after a laxative, often results before the bowels move, suggests that perhaps activation of the bowel circulation is the desideratum. When the bowel is inactive there is low activity of the liver, and, while more poison may be formed, less is destroyed (Powers and Sherwin). The proposition that the symptoms are not toxic and may be produced as a reflex by stuffing the rectum with cotton, and relieved by removing the cotton, has been shown by Ivy and others to be untenable.

The poisons themselves may cause constipation. Rettger and his colleagues at Yale (1935) have demonstrated that excised intestinal strips are paralyzed by a weak solution of indol, phenol, glutamic acid, aspartic acid or histamine, all of which may be developed by the colon bacillus. They have some evidence also that these poisons will cause depression of intestinal muscle in intact animals.

Physiology.—The haustra of the colon are for retarding purposes, and propulsion through the colon is accomplished mainly by *mass movements*, which occur only a few times a day. In these the haustra suddenly disappear for a length of several inches, and the contents form a cylinder or bolus that hurries forward for many inches or even a foot or two in a fraction of a minute. It is by such occasional propulsive move-

* For discussion of these experiments see Herter, C. A., "The Common Bacterial Infections of the Digestive Tract." The Macmillan Co., 1907, p 248 et seq.

ments that the descending and iliac segments of the colon become filled, while the contents are kept from passing into the rectum by the musculature of the sigmoid-rectal junction. The descending and sigmoid portions of the colon have little power of absorption and serve for storage, so that defecation is deferred to once or twice in twenty-four hours. In normal persons the rectum remains empty or nearly so till toward the onset of defecation, for feces in the rectum give the desire to go to stool. But in some of the constipated the rectal threshold of sensation is raised so that the feces may lie in the rectum unknown to the patient and continue to desiccate. The rectum is more absorptive than the iliac colon above it (Steggarda).

During almost the entire twenty-four hours the *function of the colon is not to propel but to retard*, so that the liquid received by the cecum becomes formed stools. When the colon does propel its contents, the method employed is a mass movement and not the ordinary form of peristalsis.

Retarding Mechanisms.—The normal ones are: (1) the terminal ileum and ileocecal sphincter, (2) the haustral constrictions of the transverse colon, (3) the tonic rings of the descending colon, (4) the narrowed rectosigmoid junction, and (5) to hold back rectal contents, the valves of the rectum and the anal sphincters. If the contents are too liquid these natural restrainers fail to function as such; with contents too dense they overretard.

The Bowel and Liver Circulation.—Little is known concerning the relation of the bowel circulation to the activities of the bowel itself. The actively contracting bowel has a vigorous circulation, the dilated bowel a stagnant one. Carnot and Glénard expressed the opinion that the main factor in increasing the activity of the bowel is an increase in the blood flow through its muscle. Anemia probably has the effect of a sluggish circulation.

Mall demonstrated that the intestine is the propulsive organ for the portal blood and the intestinal lymph. Every contraction of the intestine forces blood into the portal vessels and goes to maintain the current through the liver, and, as a

consequence, the activity of the liver. The portal blood is increased in volume by the fluid absorbed from the intestines. Cathartics that begin to act high up in the small intestine, such as castor oil and calomel, have most effect on the liver circulation; those whose activity is largely confined to the colon, as cascara and senna, have probably a minor effect.

Causes of Constipation.—Without going into detail we might say that in most cases either (1) the mass movements fail so that the contents are held unduly long with resulting abnormal desiccation (atonic constipation); (2) the colon is hyperirritable and goes into spasms which effectually block progress (hypertonic or spastic constipation); or (3) there is damming up in the rectum (rectal constipation).

TREATMENT

People naturally not constipated pay little attention to their bowels, frequently go to stool at irregular times, skip a day now and then, have loose movements at one time and hard ones at another, and have occasional foul smelling stools or attacks of gas. But they give minor heed to these irregularities. The constipated, on the other hand, may become "bowel conscious" and then are upset by any departure from what they assume to be normal. Moreover, many of them suffer from mental and physical inefficiency whenever they fail to have adequate movements. It is for these reasons that they seek help. Physicians frequently tell these patients, "There is no harm if you skip a day," but every constipated person knows that this is not true.

From the patient's standpoint, adequacy of bowel movements means stools that are passed at least once a day with ease and comfort and with the sense of complete emptying. This, then, is our aim in treatment. But the aim is not attained if our remedies go to the other extreme and cause loose or frequent stools, for these also arouse bowel consciousness and are incompatible with bowel health.

Any surgical condition that may have a direct influence on the bowels should be attended to, such as cholecystitis, appendicitis, salpingitis, rectocele, etc.

Rectal Constipation.—If on examination a substantial amount of feces is found in the rectum but the patient has no desire to defecate, or if the patient has the desire but cannot succeed because of some rectal or anal condition, the constipation is rectal. If this is due merely to the lower end of the stool becoming dried out and scybalous, so that defecation is difficult and irritating to the anus, it may be corrected by mouth doses of mineral oil. If the fault lies in irritated crypts, painful hemorrhoids, fissure of the anus, or prolapse, conditions commonly encountered, mineral oil by mouth will ensure soft feces; and the insertion of 60 cc. (2 ounces) of olive or corn oil at night, to be retained till morning, will often allay anal spasm, permit a satisfactory movement, and promote healing. Such an amount of oil can be injected readily by the patient with a soft rubber ear syringe. In addition, on arising or at other times, an anesthetic ointment of 5 per cent of ethyl aminobenzoate in petrolatum album may be inserted as far as possible into the anal opening. If these simple measures do not relieve, one needs the help of a proctologist.

Constipation with Site Above the Rectum.—The stock advice is about as follows: whether you feel like it or not, try to have a stool every morning about the same time. When the desire to defecate comes do not postpone going to stool. Take plenty of exercise. Drink freely of water.

Exercise.—This does not necessarily help the bowels. Of 745 athletic students Forsythe found 10 per cent taking laxatives, and of 100 engaged in maximal competitive athletics 18 per cent. At Columbia, among the students in required gymnasium work, Meylan found 30 per cent constipated. A number of my constipated patients have been college or professional athletes, gymnasium instructors, horsemen who spend much of their time in the saddle, and others doing hard physical work or engaging constantly in sports. On the other hand, many of sedentary habits have no constipation.

By roentgenologic study, Case and others have observed slight progress of the colon contents from vigorous abdominal exercises, but as a rule exercise is without effect on the motility

of the colon. Its value, especially if taken outdoors, lies essentially in improvement in the general vitality and of the appetite, so that the subject eats more. Whether or not special exercises for the abdominal muscles help more than general exercise there is some doubt, but one might favor such home exercises as deep diaphragmatic breathing, working the abdominal muscles in and out with the chest set, raising the knee sharply to hit the abdomen, and raising the legs while lying on the back.

Massage is sometimes substituted for exercise. But during roentgenologic examination, with deep pressure directly on the colon, Case found it impossible to force the contents of the ascending into the transverse colon, or of the transverse into the descending. In the very thin walled, where he could grip the colon heavily with the fingers, he could effect only a slight movement of the contents. In the gas filled colon only, could he shift the bolus several inches. In thin persons Alvarez could not push along the feces in the left colon. Groedel was unable to move the contents with a vibrator in full action. As the colon contents are propelled essentially by only occasional mass movements, it would seem that the value of massage lies either in the (improbable) production of a mass movement or in promotion of the circulation.

Water.—Plenty of water with the meals may hasten the arrival of the food residues at the cecum, but the large bowel does a lot of absorbing. In a number of nondigestive patients in bed I found that the ingestion of a glass of water every hour for fourteen and fifteen hours daily for one week, almost a gallon a day, did not increase the bowel movements and served merely to activate the kidneys. On the other hand, too little water may result in feces of a dried out, constipated type, especially when the contents are held in the colon unduly long, as in the constipated. Though the various foods supply a great deal of water, this is practically all necessary, according to Rowntree, for their own digestion and metabolism, even in the case of milk (Sherman excepts fruits). Therefore, besides liquid foods, extra water must be taken. However, Cowgill

et al., warn that excessive amounts of water deplete the body of vitamin B, which is a necessary element for appetite and bowel tone.

Foods.—The following sections on Foods and Bulk Producers are abstracted from the author's article in the Review of Gastro-enterology, 2:4:279, Dec., 1935:

The cause of normal defecation is food, for a bulk of undigested residue sufficient to produce distention is requisite if the bowels are to move properly. From foods ordinarily eaten the large intestine is subject: (1) to distention—by bulk of residue; (2) to mechanical stimulation—by indigestible roughage, such as bran, husks, fibers, seeds, skins, etc.; (3) to chemical or drug action—by laxative acids and their salts, as in fruits, by free fatty acids and soaps formed from the oils and fats, by other acids, by sugars, by volatile oils, by the oils and resins of spices, and by other chemical substances, among which must be included those produced by the activities of intestinal bacteria; (4) to the influence of vitamins, especially vitamin B; and (5) to allergic reagents.

Fats and Oils.—These tend to be laxative, but cannot always be tolerated in large amounts. Moreover they rob the organism of calcium with which they form insoluble soaps, and these soaps adsorb and carry out certain products of digestion (Teller). In so far as they liberate fatty acids or form soluble (sodium) soaps, fats are irritant.

Food Residues.—Some are bland or smooth, *i. e.*, mechanically unirritating, while some are believed to act as mechanical irritants and are called roughage. Hence *residues may be classed as bland residues and roughage*. Foods that leave a fair amount of bland residue are: milk, cheese, egg, particularly raw egg, white bread, macaroni, the branless cereals and potatoes. The foods on which we depend mostly for roughage residues are: the bran-containing cereals, graham and whole wheat breads, and most fruits and vegetables, especially the raw fruits and the salads and relishes. The roughage of fruits and vegetables is composed of the tissues held together by woody and bast fibers, corky epidermal tissues, seeds, hard substances

like the stone cells of pear, and other tough or hard indigestible parts. This roughage is sometimes mistakenly called "cellulose," but cellulose itself is a very bland carbohydrate with formula, $C_6H_{10}O_5$.

Rubner found that the feces of a mixed diet gave 100 Gm. of water and 35 Gm. of dry substance, while those of a vegetable diet gave 260 Gm. of water and 75 Gm. of dry substance. Thus residues increase the amount of feces, not alone by their own bulk, but also by the water that they carry. But the indigestible residues are not all available to move the bowels, for they are prone to undergo bacterial decomposition, especially in the constipated (Rose, Cowgill). Some of the bacterial products stimulate the bowel wall; others, such as indol and phenol, depress it. Cowgill and Sullivan ascertained that habitually constipated persons require nearly twice as much roughage for colon stimulation as normal people.

Weight for weight, most fruits are more laxative than even coarse vegetables, for the fruit juices contain laxative salts or form them in the duodenum. Indeed, many people who would otherwise be constipated keep to normal movements by a very moderate daily allowance of fruit, such as an orange, an apple or a dish of prunes.

In the feces of normal dogs I have found much coarse grass, hair, gravel and pieces of bone. Hoelzel mixed screws, corrugated wire and rough pieces of gold and silver with the daily diet of laboratory animals for months at a time without noticeable harm. In fact, he observed more marked lesions in the intestines from an inadequate diet. In stools from humans I have found hard seeds and much coarse food in chunks and tangled fibers, without apparant bowel stimulation or excess of mucus. Thus there is lack of proof that roughage causes pathological irritation of the bowel, and there is much evidence that the normal digestive tract can bear vegetable and even mineral roughage in large quantities without apparant harm. In many instances even large quantities of roughage do not cause the bowels to move. Therefore, the term roughage does not of necessity convey the idea of irritation, and some physi-

cians become unduly alarmed when their patients eat freely of roughage foods.

On the other hand, in the presence of a sensitive stomach or a hyperirritable bowel, and these are common in the constipated, roughage tends to irritate, and may produce hyper-tonic (spastic) constipation. In such a condition bland foods with the addition of bulk-producing drugs and perhaps mild chemical laxatives will do more good and less harm than coarse indigestible roughage foods. Whether or not roughage itself is a cause of hypersensitiveness remains an unsettled problem; but it is agreed that, under the influence of rough foods, a latent hyperirritability may become active.

Bran owes its laxative properties largely to its fiber, but, as "commercial bran" is difficult to take, the steamed or processed bran, which has softer fiber and mixes better with the contents, is the preparation offered for humans. This is less irritating but less laxative than commercial bran. Experiments on normal and constipated people have demonstrated that bran in quantities of 30 Gm. (1 ounce or about 5 tablespoonfuls) a day tends to make larger and softer movements, but usually not loose movements.

Osborne and Mendel found bran irritant to both stomach and intestines. Mann's gastrectomized dogs vomited when bran was added to their cereal diet. In Hoelzel's rats bran caused an undue proportion of infective lesions in the cecum, and in one case a perforation. On the other hand, Rose *et al.*, found no intestinal lesions in 22 rats that had been fed bran for two to four months. There have been a number of instances of obstruction of the human small or large intestine by bran balls. When the colon is hyperirritable, bran may create distress and cramps.

Some of the value of bran has been attributed to its vitamin B, but the amount of this is not great. Bran holds only about 24 per cent of the total vitamins of the whole wheat grain (Mendel and Lewis) and is about one fifth as rich in vitamin B as the wheat germ (Rose *et al.*).

Many administer bran in the form of graham or whole

wheat bread, or the natural bran-containing cereals. Cooked in these forms it is less harsh, and consequently less laxative, than even processed bran. But, according to the figures of the United States Department of Agriculture for the several flours, to obtain the daily 1 ounce of bran, one would have to consume 10 ounces of graham bread or 20 ounces of whole wheat bread, and the bran would be in its least laxative form. Of shredded wheat, five biscuits represent the fiber of about 1 ounce of bran.

To summarize, bran administered by itself is not a food but is probably an irritant drug, to be classed with cathartics. When cooked in its natural admixture with the other constituents of grain it is less irritating and less laxative. It is possibly useful when there is habitual lack of roughage in the diet, but it cannot be furnished in adequate dosage by graham or whole wheat bread. It is contraindicated in such irritative conditions as gastric hyperacidity, colonic hyperirritability and mucous colitis.

Bulk Producing Drugs.—There is no line of division between foods and drugs and we pass readily to those drug substances prescribed to add bulk to the colon contents.

The bulk producers are of two kinds, the *bland* and the *roughage*. The bland group includes agar, bassorin, tragacanth, hulled psyllium seed, cellulose and mineral oil. The roughage group is represented by whole psyllium seed and flaxseed. All the bulk producers increase the bulk and the softness of the colon contents, not so much by their own volume, but largely through their ability to carry down water and hold it against the absorptive powers of the colon. All except mineral oil are dry and must be accompanied by abundance of water. Nearly all of them make a viscous mucilaginous substance that in large amounts may have detrimental effects throughout the alimentary tract. Mostly they do not hasten passage through the tract, but merely make the stools softer and bulkier. They do, however, carry down the residues with greater uniformity.

As the dry bulk producers are all prescribed by spoonfuls and differ markedly in weight, comparisons must be made on a volume dosage, and not on that of weight. Therefore, of

several of them I have taken one measured drachm of the dry substance and measured it after it had soaked in water for twelve hours and the surplus water had been drained off. If the wet bulk of a given measure of dry flaked agar saturated with water is represented by 1, that of granulated agar is 3, of powdered agar $5\frac{1}{2}$, of whole psyllium 10, of hulled psyllium 14, and of bassorin 29. The agar are rather dense and coherent, the bassorin stools soft, and interspersed with jelly-like particles, while those from both whole and hulled psyllium are of a tenacious, tough and rubbery consistency that suggests difficulties for the churning and absorptive functions of the bowel. From hulled psyllium we have seen a stool in a single elastic piece 15 inches in length. The stools of whole psyllium regularly contain many unchanged seeds, which constitute roughage.

Mineral Oil.—This valuable softening agent does not coat the intestinal wall to serve either as a protective or as a lubricant, but is mixed with the contents, usually in emulsified form. Its stools contain much more water than normal (Newman and Gruenfeld, Schlagintweit), so it is a bulk producer. It proves especially valuable in conditions of hyperirritability of the bowel, in hemorrhoids or other anal irritations, and in those whose feces tend to form conglomerates or hard scybala. In intestinal toxemia it may be beneficial by carrying out some of the oil-soluble poisons of putrefaction, notably indol, skatol and phenol.

But mineral oil is not harmless, for it coats the particles of food and retards their digestion, it interferes with the absorption of the products of digestion and, according to Mellanby, it prevents the reabsorption of bile from the intestines. But more important still is the fact that it is practically unabsorbable by the bowel and consequently carries from the body some of the substances that are soluble in oil, such as the vitamins A, D and E. DaCosta and Carlson report that adult rats on mineral oil failed to reproduce owing to the depletion of vitamin E. Dutcher *et al.*, Rowntree, Jackson and others have found that mineral oil, in doses comparable with those given

to humans, killed rats on a minimal vitamin A diet. The possibility of mineral oil creating avitaminosis in the debilitated, in nursing mothers and in growing children cannot be ignored.

Yet it has been found that depletion can be avoided by a moderate increase in the butter fat, and by administering the oil separately from the food. In butter fat vitamin A is represented largely by its precursor, carotene, which has more affinity for mineral oil than for the lipids of the intestinal contents. The opposite is true of vitamin A itself. With cod liver oil and its concentrates, mineral oil results in no appreciable loss of vitamin A.

The Chemical Laxatives.—Hurst writes, "An excessive quantity of coarse indigestible food probably does more damage to the mucous membrane (of the bowel) than a mild chemical irritant." In chronic constipation, the useful drugs are limited in number, those employed being mostly small doses of the saline cathartics (especially the mineral waters and milk of magnesia), the tonic laxatives or anthraquinone drugs (cascara, senna, rhubarb, aloes and aloin), and phenolphthalein. Any of these may cause griping, especially in a hyperirritable colon. The salines produce abnormal stools and cannot be continued indefinitely. Phenolphthalein is partly absorbed and some of it is reexcreted in the bile, therefore its action tends to be prolonged, and it is more prone than the tonic laxatives to make undesirable loose stools. This is especially the case with its mineral oil admixtures. Aloes is harsher and more active than aloin. Rhubarb is very mild. The drastics, such as jalap, colocynth, gamboge, scammony and podophyllin, which irritate the entire digestive tract and may produce inflammation of both the alimentary tract and the kidneys (drastic action), are not applicable in chronic constipation.

There are undoubtedly many instances where the use of chemical laxatives is a necessity, at least for a time. When hyperirritability does not predominate, the tonic laxatives are most useful remedies. Their chief action is on the large intestine. They do not produce inflammation in the intestines,

and if their active principles are absorbed the kidneys are not injured. They may be taken for years without the need to increase the dose; indeed often this may be reduced gradually till the drug is dispensed with altogether or needs to be taken only occasionally.

We have found particularly useful the preparations of agar and bassorin with cascara. Another well-tried prescription of the author is: *sodii bicarbonatis*, 12 cc. (3 drachms), *fldext. cascarae*, 8 cc. (2 drachms), *mist. rhei et sodae comp.*, N.F. q.s. ad 120 cc. (4 ounces). M. et Sig. Two teaspoonfuls with a glass of water an hour before lunch and dinner and at bedtime. This is the empty time of the stomach, a better time for the administration of an antacid mixture than at meals. Frequently it is not long before half the amount is effective, and shortly thereafter the bedtime dose alone, or a dose once a week.

A palatable remedy of which a small dose may be taken before or after each meal is: \mathcal{R} *fldext. cascarae aromat.*, *fldext. sennae*, *tinct. rhei aromat.*, of each equal parts. It may be made up to teaspoonful doses with the vehicle, *isoalcoholic elixir*, N.F.

Enemas.—These may be used occasionally, and if atony of the rectum or lack of sensitiveness cannot be overcome may have to be employed indefinitely. I have encountered two persons who had used a daily enema for some forty or fifty years and seemed in good general health. The roentgen use of the barium enema, which is denser and more viscous than a normal enema, has demonstrated that under two feet of pressure such an enema reaches the cecum in two to five minutes, that as a rule 1000 to 1500 cc. will fill both colon and rectum, that not infrequently there is a leakage backwards into the ileum, and that at the subsequent defecation almost the whole colon except the cecum, and at times the cecum also, may be emptied almost completely. Such an extensive filling and emptying for defecation is unphysiological. After a barium enema, roentgenologists have frequently noted spasms and undue activity in some part of the large bowel, but mostly these occur only in patients with hyperirritable colon.

Except in rebellious cases the enema should not contain irritants such as soap. In 6 of 20 men to whom 0.5 per cent soapsuds enema was administered by Runge and Hartman, occult blood appeared in the stool within three days; and in all of 16 rabbits an enema of the same soapsuds caused ulcerations and diffuse ecchymoses. Alvarez states that powerful contractions are produced when the colon is filled with soap water and then tied off a little above the anus. With the sigmoidoscope, I have seen marked hyperemia following a soapsuds enema, a condition that I have never encountered after an enema of plain water or physiological salt solution, which may be considered the proper liquids for ordinary use.

Finale.—If we believe that constipation has profound effects upon the efficiency and the disposition we cannot feel that we have fulfilled our responsibilities by a mere laxative prescription. Always the general vitality and appetite should be promoted. All should be water drinkers. In a goodly number satisfactory movements may be continued indefinitely as the result of improved diet habits; in others, food regulation alone does not suffice. In many instances, the treatment is simplified by the use of bland bulk producers; yet, if required in large amounts, these have deleterious effects on all the digestive processes and result in stools that are far from physiological. As time goes on we learn that in some of our patients both foods and bulk producers eventually fail, and the good results can be maintained only by chemical laxatives; indeed, chemical laxatives, properly used, together with food regulation, may lead to cure. In still others completely satisfactory movements are not obtained no matter what measures we try. By long experience we become convinced that some people are so unendowed by nature that they cannot be cured and must depend on laxatives throughout life.

No permanent benefit results from medication "as necessary," for the result of this is a large dose one night because the bowels have not moved enough, and a small dose or none at all the next night because they have moved too much. This

procedure never results in cure. Of artificial aid the bowel should receive the same each day.

A fairly large percentage of constipated patients have hypersensitive digestive tracts, which render them unable to take with impunity even the normal amount of roughage, or even, perhaps, fruit juices. They require bland food, bland bulk producers and carefully selected chemical laxatives. Sometimes belladonna or atropine is a valuable addition. Frequently with their constipation these patients manifest psychic disturbances, gastric hyperacidity, hyperirritable colon or mucous colitis, conditions that present complex problems for management.*

In any event experience teaches that because of undesirable reactions from coarse indigestible foods, of stomach irritation from acid fruits, of a distaste for vegetables, of rebellion over the long continued use of bulk producers, or for some other reason, many will eventually return to the chemical drug laxatives, and frequently to patent medicines. Let us not precipitate this crisis ourselves by prescribing at the outset proprietary mixtures with trade names, under which the patient learns to purchase them over the druggist's counter.

CLINIC OF DR. M. JOSEPH MANDELBAUM

FROM THE BRONCHOSCOPIC CLINIC, HOSPITAL FOR JOINT
DISEASES

ASTHMA: TREATMENT BY INTRATRACHEAL INJECTION OF IODIZED OIL

With an Analysis of 1000 Compiled Cases (Including 114 Newly Reported Cases)

Few diseases have had a greater number of remedies offered for their cure than asthma. While in a certain number of cases, a few of these means have had a palliative effect, such as temporarily reducing the severity and even the frequency of the paroxysms, still fewer have successfully run the gauntlet of time and experience. Most have been eventually thrown into the discard, with perhaps epinephrine alone, among the modern remedies presented for the treatment of this very distressing disease, remaining outstanding in its influence, though, also, mainly in a palliative manner. In one other group of asthmatics, a limited group of allergic origin, desensitization has occasionally proved of value, but this has usually required repeated seasonal administration. Therefore, whenever a new remedy presents itself for consideration, and particularly if repeated favorable reports are noted, as in the use of intratracheal instillation of iodized oil, further investigation is warranted.

The increasing interest in and use of the intratracheal injection of iodized oil for asthma is the stimulus for this paper, which comprises a critical study of almost all of the papers already published and of several as yet unpublished articles

which, through the permission of the authors, have been included in the statistics of this report, as well as of 114 cases of my own, the total number of cases represented being 1000.

Sources of this Compilation.—The following are the sources from which the 1000 cases herein reported were obtained:

Reference.	Year.	Author.	Number of cases reported.
1	1932	Taylor, J. H.	2
2	1932	Fink, L. W.	13
3	1932	Anderson, W.	60
4	1933	Cole, D. B. and Harper, E. C.	26
5	1933	Alison, J. P.	10
6	1933	Harris, M. C. and Turkel, H. L.	50
7	1934	Balyeat, R. M. and Seyler, L. E.	100
8	1935	Balyeat, R. M. and Seyler, L. E. and Shoemaker, J.	50
9	1936	Penta, A. Q.	50

			1000

The direct intratracheal instillation of various medicaments for divers bronchial affections is not new, however, for, as I recalled in a previous paper in 1932¹⁴ nearly one hundred years ago Horace Green,¹⁵ of New York, had already instituted the intratracheal instillation of remedial agents for therapeutic effect. Although many others, notably of the French School, reported on the use of direct intratracheal therapy during the century just mentioned, it was not until Forestier and Leroux's announcement in 1922¹⁶ that iodized oil was a safe bronchographic medium, that a new and widespread interest in this method was reactivated.

In 1924,¹⁷ the author devised a styletted catheter for instilling iodized oil into the trachea and in 1928¹⁸ published a description of a finger-holder for a laryngoscopic mirror which made it possible for the operator to introduce fluid media into the trachea positively, safely, and with comparative ease.

Review of Literature.—Before presenting the cases and the method used by my associates and myself, let us review as briefly as possible the literature of direct intratracheal therapy before the advent of iodized oil.

Horace Green¹⁵ began the use of direct intratracheal injections of solutions of silver nitrate for pulmonary tuberculosis and other forms of bronchopulmonary disease in 1835. In the succeeding decades, others contributed to the subject of direct intratracheal injection of therapeutic media for various bronchopulmonary affections, as follows: Alison in 1853,¹⁹ Fullgrave in 1885,²⁰ Willis Anderson in 1900,²¹ Delor in 1901 to 1902,²² Tiphine also, in 1901 to 1902,²³ Willis Anderson again in 1902,²⁴ McKinney in 1903,²⁵ Richardson in 1904,²⁶ Meltzer in 1912,²⁷ Winternitz and Smith in 1919^{28, 29} and in 1920,³⁰ Boirac in 1920,³¹ Lehmann in 1922,³² Castex³³ and Mitelette in 1924,³⁴ Marty in 1925,³⁵ and Pare in 1927,³⁶ Turner in 1928,³⁷ Mounier-Kuhn in 1928,³⁸ Menager in 1929,³⁹ Pallestrini and Albanese in 1931,⁴⁰ and Spoto in 1931.⁴¹

In 1923, Forestier and Leroux⁴² reported further on the value of intratracheal injections of iodized oil. Subsequent investigators noted that a beneficial therapeutic by-effect resulted from the use of iodized oil in a variety of bronchopulmonary diseases.

For those interested in a consideration of iodized oil from the historic, therapeutic, and bibliographic standpoints, Sicard and Forestier's work,⁴³ *The Use of Lipiodol in Diagnosis and Treatment*, is recommended. American literature is too replete with excellent bibliographies regarding the use of iodized oil for both diagnostic bronchography and as a therapeutic medium in conditions of the bronchopulmonary tree other than asthma, for a full list here. Pritchard, Whyte and Jordan,⁴⁴ in 1926, and Ochsner in 1926⁴⁵ and again in 1929,⁴⁶ called the attention of the profession to the beneficial effects following the intrabronchial injection of iodized oil in various types of bronchopulmonary disease. But Taylor¹ and Fink² and Willis Anderson⁵ in 1932 were the first to publish papers in the United States on the use of iodized oil in bronchial

asthma by intratracheal injection. Taylor, in June, 1932,¹ cited 2 cases of bronchial asthma, which, after the therapeutic instillation of a number of iodized oil treatments, showed definite improvement with a reduction of the frequency of the asthmatic seizures.

In August, 1932, Fink² published the results of the use of intratracheal injection of iodized oil in 13 cases of bronchial asthma, and stated his conclusion that results were in proportion to the extent and duration of pathology.

In November, 1932, Anderson³ reported the first large group of cases—60—of bronchial asthma, in which iodized oil only (lipiodol) was the medium used by intratracheal injection. A considerable number of these cases had suffered from childhood, and most had been afflicted for more than four years. Anderson's research extended over seven years. About one half of these cases were allergic in nature and the other one half were activated by peripheral, psychic or acute infectious respiratory causes. Satisfactory results were reported in all of the cases. Twenty-four were completely relieved from one to five years; the remaining 36 were definitely relieved following treatment from three to twelve months.

Cole and Harper, in April, 1933,⁴ reported 26 cases of bronchial asthma treated by iodized oil injections. Fourteen were markedly improved; 12 were benefited in varying degree. Cole and Harper stated that all cases had been improved, that none showed any ill effect, and many had been relieved of their asthmatic attacks after the initial treatment. In this year, Alison⁵ also reported 10 cases of bronchial asthma treated by the use of iodized oil, in all of which excellent results were obtained. Harris and Turkel⁶ likewise in this year began the use of iodized oil for asthma. These authors selected 50 of the most difficult cases they could find in two separate institutions, as well as in private practice. Lipiodol was the form of iodized oil used. They made a particular study of the etiologic factors in their series, classifying the cases as follows: 20 as infectious, 8 as allergic, and the remaining 22 as giving evidence of focal infection associated with a history of

clinical hypersensitiveness substantiated by skin tests. The ages varied from twenty-two to sixty-four, and all had received routine continuous treatment subsequent to the iodized oil instillation for a minimum of three years. In 4 cases, the results were excellent, *i. e.*, after several months of treatment the patients remained asthma-free for more than a year and a half. Eight cases obtained little or no relief; 14 were partially relieved; 28 were relieved; 75 per cent or better.

Anderson reported in 1936¹⁰ a total of 360 cases of asthma treated with iodized oil, combining in his summary the 60 cases originally published⁸ and 300 patients subsequently treated by this method. Not only has he had the largest experience with this method, but the excellent results he has obtained have undoubtedly been due to meticulous study he makes of his cases as well as the great caution he exercises, particularly in the serial mode of injection of the various lobes. He first injects one lower lobe, then one week later the opposite lower lobe, to determine the presence and location of tubal obstruction. The lower lobes are injected first inasmuch as these are most frequently involved. In his cases bronchiectasis was not usually extensive. The oil, Anderson states, should reach the alveoli in from seven to fifteen minutes. If not, complete or partial obstruction is present; this obstruction being due, in his opinion, to bronchospasm, edema of the mucosa, or excessive secretion. To differentiate, a hypodermic of 10 mm. of adrenalin is given one-half hour after the injection and the patient examined fluoroscopically. If the obstruction is due to bronchospasm, it will have been relaxed by the adrenalin or the edema thereby reduced, so that the oil will have descended into the vesicles. Ten to 20 cc. is generally sufficient for one lobe. After the initial injection, both lobes may be injected simultaneously, for which 20 to 30 cc. may be required.

If the oil does not pass quickly into the alveoli, it will be expelled more rapidly, much within twenty-four hours, when subsequent injections may be given more frequently, with safety. Dependence upon the rate of expulsion of the oil,

which varies in the individual case, is important, as otherwise overloading of the tissues may ensue. At no time should the amount of oil be sufficient to reduce the vital capacity more than 50 per cent; this may induce more severe and more frequent attacks, even severe cyanosis. When oil promptly reaches the alveoli, indicating freedom from excessive secretion, the amount of oil injected and the frequency of injection should be diminished. If no improvement is seen after several injections into lower lobes and one is assured that the oil has reached the alveoli, one lobe at a time should be treated and effect noted. If no relief follows, treatment is continued until the entire bronchial tree has been washed out with the oil until improvement has resulted, unless some contraindication should arise. Response varies. Some patients respond immediately, others gradually, and some not for many months, when sudden improvement is noted. The young respond more rapidly, as a rule, than the old; those whose asthma followed a respiratory infection such as bronchitis, whooping cough or pneumonia, measles or influenza, respond more slowly than the allergic types. Ninety per cent of the cases of asthma complicated with bronchitis were rapidly relieved of the latter. Reduction of clinical sensitiveness to excitants and stimuli was also noted. In some, clinical sensitiveness promptly disappeared, although skin tests remained positive. A reduction of 75 per cent in susceptibility of these asthmatics to colds was noted, following iodized oil treatment.

Penta, in 1936,⁹ reported that in a series of 50 cases of bronchial asthma treated over a period of six months with instillations of lipiodol, 40 per cent obtained a symptomatic cure; 25 per cent have shown definite improvement as manifested in the greater interval between the attacks as well as in the marked reduction of severity. The remaining 30 per cent have shown little or no improvement. Penta's routine is to instill the oil (20 cc.) every week for a period of two months and then gradually increase the interval between treatments, individualizing cases. At the end of the fourth month most of his cases were receiving the oil only once monthly.

Author's Cases.—The following 114 cases reported by the writer of this paper comprise an unselected series from hospital and private practice over a period of ten years and upon an experience of twelve years in the practice of direct intra-bronchial therapy.¹⁴

Total number of cases treated	114
Total number of cases unable to follow-up	17
Total number of cases with follow-up to date	97
Total number of cases with complications	4
Total number of deaths	0
Sex: males 86; females 28.	
Youngest patient: eight years; oldest, seventy-seven years.	
Least number of injections needed to relieve, 1 (in 3 cases).	
Maximum number of injections needed to relieve, 84.	
Average number of injections given	37
Average duration of treatment	5 months
Average amount of iodized oil used in successful cases . . .	684 cc.
Maximum amount of iodized oil used in any case	840 cc.
Average intervals of treatment, six days.	
Longest period of treatment: two years and four months.	

Of the 38 cases treated in the first five-year period, 9 had recurrences: 2 in the sixth year, 3 in the seventh year, 1 each in the eighth, ninth and tenth years. Upon resumption of treatment, 7 of these 9 recovered quite promptly. The other 2—1 recurring two and the other three years after the original series of treatments were completed—continued to have asthmatic paroxysms, though not nearly so severe or as frequent as formerly.

Bronchograms were made in 76 cases. Of these, 36 had definite bronchiectasis in varying degrees. In 23, the demonstrable bronchiectasis was limited to the lower lobes. In 5 cases, only the right lower lobe was involved; in 10 cases, both lower lobes; in 2 cases, only the right middle lobe. In the other 6, combinations of lobes, mostly lower and middle right, were present. In only one instance was an upper lobe alone involved, the right. In 2 cases, the lower left and middle right were affected.

The bronchiectasis was mainly of a cylindrical type. In a few cases only was it saccular. In approximately one fourth

of the cases it was of a mixed type, *i. e.*, combined saccular and cylindrical. Only 1 case of asthma due to foreign body was found in this series. The patient was a boy of ten years with a small piece of peanut kernel in the upper left main bronchus; when this was removed he promptly recovered.

Of the 97 cases with a satisfactory follow-up, only 32 have been free from attacks long enough to be classified as cured, that is, with no recurrences and no treatments of any kind for three years or more. Of the remaining 65 cases, 38 were only slightly relieved or not aided at all after nine months of treatment and the other 27 cases are still under treatment. In the latter group, 11 who have been under treatment for more than eight months are definitely improved.

Of the 97 faithful to treatment, 18 reacted to the various allergens, mainly the pollens, a few to dust alone, and about one quarter to both dust and pollens. Of these, 14 had received prolonged desensitization treatments without any relief of their paroxysms, while the others who reacted positively to allergens had had no allergic treatments. Eleven of the 97 had nasal polyposis in varying degree. Approximately one half of these patients (5) were relieved only after the iodized oil injections were resumed following removal of the nasal polyps. The remaining 3 were not relieved either before or after the polyps were removed.

Direct bronchoscopic cultures were taken in only 19 cases. These showed a variety of organisms and the results of the treatment by iodized oil were not seemingly affected by the nature of the bacterial flora.

Twenty-five cases had paranasal sinusitis, 16 of whom improved only after sinus treatment.

Contraindications.—In patients sensitive to iodine, developing marked local effects or rashes or other constitutional or local symptoms following its therapeutic administration by any method, iodized oil should be used very cautiously and, then, in very small amounts only. Those definitely susceptible to iodism should not be subjected to any form of iodine therapy. Anderson¹⁰ believes that all prospective patients for

this form of treatment should be previously tested for iodine sensitiveness.

Treatment with iodized oil should not be instituted in patients whose asthmatic attacks are due to growths within or without the bronchi. Most observers believe that a considerable percentage of asthmatics are suffering from certain etiologic factors which, while they produce asthmatic seizures, are only curable in some instances by removal of the cause. Thus, individuals with either intrabronchial or intrapulmonary neoplasms determinable only by roentgen and bronchoscopic study, would not be proper subjects for the use of iodized oil treatment even though these conditions be associated with asthmatic paroxysms. Malignancies, particularly carcinoma, must always be thought of, as well as nonmalignant neoplasms of the bronchopulmonary tissues. Other lesions causing obstruction to free bronchial drainage, whether foreign bodies causing obstruction to free bronchial drainage, or abscesses, tumors, cicatricial distortions, etc., mediastinal growths, pleuritic effusions or neoplasms, causing extrabronchial pressure—all are to be kept in mind, particularly during the early stages of so-called "asthma." This type of treatment should not be undertaken, moreover, in cases of acute pulmonary abscess, severe hemoptysis, or in patients with unknown causes of fever or in the acute stages of grippal respiratory disease in either the upper or lower air passages.

Anesthesia.—Anderson¹⁰ uses no preliminary morphine or other sedatives. Most writers agree that both the cough and swallowing reflex must be completely abolished during the treatment. This is accomplished by means of a variety of local anesthetics. Anderson sprays the pharynx and anterior and posterior tonsillar pillars with 2 per cent nupercaine solution and drops 2 to 3 cc. of a 5 per cent solution into the larynx. He reports no toxic symptoms in more than 2000 injections.

Balyeat and associates⁸ give the patient a preliminary dose of adrenalin—in some cases, adrenalin and $\frac{1}{8}$ grain of morphine if the patient is wheezing at the time the oil is to be given. They favor 1 per cent solution of cocaine hydrochloride

which, when the patient is asked to breathe deeply during the spraying, suffices to anesthetize the pharynx and trachea. In patients with very sensitive throats, they advocate the additional use of 10 per cent solution of cocaine to each subtonsillar region, which also abolishes the swallowing reflex.

A number of operators are able to instil the oil into the patient's larynx without any anesthesia at all, after a few times.

Ochsner,⁴⁵ Anderson,¹⁰ Balyeat,⁸ and Harris and Turkel,⁶ after experimenting with several types of anesthesia, concluded that the application of 4 per cent solution of cocaine to the posterior wall of the pharynx, the base of the tongue, the uvula and the faucial pillars was simple and efficacious. For the larynx, a 10 per cent solution of cocaine was employed—in several cases directly to the larynx, by an applicator. In most instances, the spray was found satisfactory.

Instrumentarium.—The only two methods worthy of consideration are the bronchoscopic and the nonbronchoscopic. The former is of value in those cases where the irritability of the lower air passages is so great that oil injected by other methods is immediately expelled or not retained long enough to be of value. This method also permits introduction of the oil into a specially desired bronchus via a long catheter passed through the canal of the bronchoscope. The transcricoid needle method of injection, which I condemned shortly following its introduction for this purpose, I am happy to state has been abandoned. For the nonbronchoscopic means, a large choice of instruments are offered, mainly of two types: the syringe cannula and the bronchial catheter methods.

While a greater preference is shown to some form of cannulated syringe, because of its relatively easier adaptability to the average operator's manual dexterity, it can be readily demonstrated that the bronchial catheter, particularly the styletted type (Figs. 76, 77), possesses definite advantages that warrant its adoption for more general use. First, it permits the introduction of the tip of the catheter between the vocal cords under direct vision, and secondly, one is assured before injecting the oil that the catheter is definitely in the

trachea, thus assuring the operator that the oil is being injected into the bronchi and not into the stomach. Third, in bronchography, which is such an important preliminary procedure in the proper conduct of this treatment, the patient with the soft catheter between his lips can assume any position necessary to inject the oil into a particular bronchus with comfort, and permits the only satisfactory method of perform-

Fig. 76.—Stylet for author's tracheobronchial catheter.

ing bronchographic fluoroscopy. The tip of the catheter can be introduced to the openings of any of the primary or secondary bronchi while the patient is under the fluoroscope, either in the standing, oblique or horizontal postures, and it can be held in the trachea for prolonged periods of study, and varying amounts of the iodized oil can be injected into a number of desired bronchi at one sitting, either in one or both sides of

Fig. 77 -- Author's tracheobronchial catheter and stylet assembled.

the chest. Satisfactory results, however, can be obtained with one of the many forms of iodized oil syringes with attached cannula having a laryngeal curve. For this purpose the author in 1924 devised a well-balanced syringe (Fig. 78). It has a cannula with a flattened distal end, well-rounded to prevent irritation or damage to the vocal cords, and a slotlike opening permitting easy egress of the oil without using any force in

ejecting same. After preliminary anesthesia, gently hooking the end of cannula over the epiglottis, and permitting it to rest on the vocal cords, it will without any force, slip by its own weight between the cords into the trachea, when the oil can be gently expelled by gravity, drop by drop, into the desired bronchus. The use of this latter type is so well known that I will describe the styletted catheter method used in our intratracheal medication, as well as our method of preparation and anesthesia.

Preparation of Patient for Treatment.—In a well-considered routine it is most essential that a searching history, a careful physical examination, in most cases a preliminary roentgen chest examination and in some cases both roentgen and preliminary bronchoscopic examination, be undertaken.

Fig. 78.—Author's iodized oil syringe.

Wassermann tests, sputum examinations and hematologic studies are all indicated at times.

Almost all writers agree that upper respiratory infection plays a large rôle in bronchial asthma. Thus roentgen and clinical examination of the paranasal sinuses are important. The association of nasal polyposis with a number of cases of asthma is recognized. The association of allergenic factors must be kept in mind even though certain writers, especially Anderson,¹⁰ states that disregarding allergic elements he has had splendid results from iodized oil treatments alone.

Experience has shown that the early morning before breakfast is the best time, as, following a good night's rest, induced if necessary by a well-selected hypnotic, the patient's nerves are most quiet and it is easier to obtain his most helpful co-operation, in addition to which, the empty stomach avoids

nausea which occasionally interferes with smooth progress of the procedure. Postural drainage treatment is not necessary unless the case is complicated by bronchiectasis. In 1927⁴⁷ the author gave a complete résumé of this valuable adjunct to help relieve the lower air passages of excessive secretions.

The patient is permitted nothing after midnight preceding the morning of the treatment. Some cases may require a sedative such as a barbitol preparation an hour or two before the treatment. Certain extremely nervous types may even require a hypodermic of morphine a half to one hour before the treatment, much as one does preliminary to tonsillectomy under local anesthesia. Local anesthesia may be induced by one of the many means in vogue, the choice of either cocaine, nupercaine or similar drugs, as well as the method of application and the strength of the solution used being left to the operator. So-

Fig. 79—Author's pyriform sinus applicator for carrying anesthetic-soaked cotton.

lutions of cocaine vary from 2 to 10 per cent, and nupercaine from 1 to 3 per cent, according to the type of patient, as toleration to instrumentation of the throat varies greatly. Some patients do very well with a simple spraying of the throat and hypopharynx with 2 per cent cocaine solution, while irritable types may even require a preliminary hypodermic of morphine sulphate $\frac{1}{4}$ grain with atrophine sulphate $\frac{1}{150}$ grain in addition to a careful local swabbing of the throat and hypopharynx with 10 per cent solution of cocaine.

For general use, our routine is to apply a specially curved, cotton-tipped pyriform-sinus applicator which we devised (Fig. 79) moistened with freshly made 10 per cent cocaine solution, and to insert it in each pyriform sinus, first one side, and then the other. It should be held in position in each side from five to ten minutes, and after an interval of ten minutes, the pro-

cedure should be repeated. This is practically the same method utilized for local anesthesia preceding bronchoscopy. Inasmuch as this procedure requires the prolonged retention of the catheter in the tracheobronchial canal, it is best also to instill a few drops of warm 2 per cent cocaine solution upon the vocal cords as well as between them into the tracheal canal. The laryngotracheal cocaine syringe devised by the author (Fig. 80), has a curve particularly adapted for this procedure. After waiting a few minutes for the anesthetic to take effect, one is ready for the introduction of the tracheobronchial catheter. The wire stylet is anointed with sterile oil (such as olive oil, albolene or lipiodol) before slipping it into the catheter, to permit its easy withdrawal later, when the catheter is in situ. With the patient sitting in the usual position for laryngological

Fig. 80.—Author's laryngeal cocaine syringe for dropping anesthetic solution upon vocal cords and into trachea.

examination, and the laryngoscopic mirror in place, either the patient himself, or an assistant holds the extended tongue. Holding the patient's tongue in the proper position is, perhaps, the most difficult part of the entire procedure. To hold the laryngoscopic mirror in one hand and the handle of the stylet-catheter in the other while trying to insert its tip between the vocal cords of the patient with someone else endeavoring to hold the tongue in the proper position, either an assistant or the patient himself, is very difficult for a great number of physicians. So, in 1928,¹⁸ I devised a special "finger-holder" for the laryngoscopic mirror which is admirably adapted for this purpose (Fig. 81). The tip of the stylet-catheter is inserted between the vocal cords while the patient is asked to take a deep inspiration. Before doing so, it is wise to explain to the patient that it is rarely possible to successfully intro-

duce the catheter at the first attempt so that he will not be too easily discouraged and to retain his cooperation. As soon as the instrument has passed several inches below the cords, immediately let go of his tongue and gently, with one hand fixing the position of the catheter at the upper teeth, and with the other grasping the proximal end (the handle) of the stylet, withdraw it.

The catheter is quickly and most gently slipped further down toward the carina of the trachea and the wire stylet withdrawn, the patient is told to firmly close his lips upon the catheter and to breathe slowly and regularly through his nose. If you fail upon your first attempt to pass the intratracheal catheter, or if in some patients it passes into the esophagus the

Fig. 81.—Author's finger-holder for laryngoscopic mirror.

first time it is essayed, simply withdraw it gently and wait a few moments before reintroducing it.

After the stylet is withdrawn from the catheter, tell the patient to fix the position of the instrument by compressing his lips firmly against it (not the teeth). Then, to be certain that the catheter is properly placed in the trachea, if the proximal end of the catheter is put close to the operator's ear, one can hear the patient breathing through the tube. Then, connecting the previously filled syringe with the required amount of warmed iodized oil, one can inject the oil slowly and with certainty into the desired bronchus, according to the posture the patient is told to assume. For the first injection, bronchographic fluoroscopy is always done, immediately followed by a roentgen study of such films as the individual case may require.

Previous Types of Treatments.—Anderson¹⁰ states that many of his 360 cases treated with iodized oil had previously been treated with all the conventional treatments with little or no results. No other treatment was given by him excepting occasional use of adrenalin for the immediate relief of an attack. Balyeat⁸ reports that most of his cases were of the intractable type and poor results were obtained in many of these patients by the usual methods of treatment.

Penta⁹ states that his experience showed that patients over thirty years of age who are suffering from bronchial asthma will not be benefited by any form of allergenic treatment.

Frequency and Intervals of Injections.—Penta⁹ instills 20 cc. every week for a period of two months, then gradually increases intervals (depending on course of individual case). Most cases at end of fourth month get oil once a month.

Anderson¹⁰ injects 20 cc. into the lower lobe bronchus of one side and one week later, providing no untoward reaction follows the first injection, follows with a second similar injection into the lower lobe of the opposite side. He advises frequent fluoroscopies to guard against overloading the alveoli with oil. Never more than 50 per cent of the vital capacity should be reduced. It may increase frequency of attacks and produce cyanosis. If after several injections in lower lobes no improvement follows, then follow same procedure in middle and lower lobes. When improvement is noted, gradually reduce amount of oil and increase interval of treatments. When attacks cease for 6 months, cease treatments until recurrence, and then renew injections.

Balyeat⁸ and associates first instil 20 cc. in one side, take a roentgen film, and the next day repeat the procedure on the other side. If case is treated, 10 cc. of oil are given on each side about four days later, from then on once a week. After a number of injections have been given, the interval is increased to a two-, three-, or four-week interval, or even longer, according to the individual needs of the case. In establishing their routine, they tried various intervals, but found weekly intervals sufficed.

Harris and Turkel^o administer 20 cc. of the iodized oil weekly until definite improvement is noted, then every two weeks, until further improvement, when the interval is increased to one month. When no improvement was noted after six weekly injections, treatment was discontinued and resumed six months later.

Reaction Following Injection.—The oil is well tolerated in most patients. In some a convulsive cough may result lasting from half an hour to several hours. It may be mild, very severe, or even produce a violent asthmatic paroxysm. As little as 2 cc. may cause this. In others too rapid injection of the oil may cause dyspnea or even acute collapse of the lung.

Some asthmatics with a complicating chronic laryngitis, tracheitis, or bronchitis have an easily excitable cough reflex, and as soon as the oil contacts the mucosa, it is expelled by a severe coughing paroxysm.

A chill, rise of temperature, increased pulse rate and pain in the injected area may occur in some cases. Acute iodism occurred in only one of our cases. It followed the first injection of a female of eighteen, causing a transient though enormous swelling of the thyroid.

It occurred in 8 of Anderson's 360 cases, and being susceptible to iodism, the treatment was discontinued. No chronic iodism occurred even in cases where large aggregate amounts were injected over long periods.

There were 8 cases of pneumonia in this group. Five of bronchopneumonia; four of these recovered and one died. Three were lobar pneumonia in aged individuals, all of whom recovered. x-Ray examination of the seven who recovered showed considerable oil in the lungs. Treatment in four of them was continued for months without recurrence of pneumonia.

In our 114 cases, 1 case of transient bronchopneumonia followed the third injection. This patient, female, thirty-four years old, recovered in a few days without any special treatment. We believe this was due to the fact that the patient

was in the initial stage of a grippal infection and therefore we thereafter refused to inject any patients suspected of developing a fresh cold or already advanced in the early stages of an acute nasobronchial infection.

Precaution.—If the iodized oil is accidentally injected into the patient's stomach, remove at once via the stomach tube and give a brisk cathartic.

Fatalities.—The possible dangers of iodism from the use of iodized oil has already been reported by Firth,⁴⁸ Carmichael⁴⁹ and Eller,⁵⁰ and other untoward effects following the injection of iodized oil into humans were well presented in 1932 in the Journal of the American Medical Association.⁵¹

The first death, however, directly attributable to the injection of iodized oil was reported by Macdonald in 1932.⁵² In this case death followed the injection of 20 cc. of iodized oil. The fatality was considered due to the patient's sensitiveness to iodine. The second death directly attributable to the intrabronchial instillation of iodized oil was recently published in the Journal of the American Medical Association by Goldstein.⁵³ A male patient of forty-three years received a lung injection of 20 cc. of iodized oil for diagnosis. Films showed no bronchiectasis. Next day a papulopustular eruption appeared on his face, then spread to chest, arms and hands, and following nausea, the patient became stuporous from a severe toxemia. The oral mucosa showed vesicobullous lesions. Urinalysis revealed an acute glomerulonephritis. In spite of treatment, the iododermatous lesions spread over most of the body and the nephritis became more marked and death ensued twenty-six days after the onset.

He concluded that despite the negligible absorption of iodine by the bronchial mucosa, it is entirely conceivable that in a markedly sensitive or allergic individual a sufficient quantity could have been absorbed to be responsible for the eruption and that death ensued as a result of a nephritis plus an overwhelming toxemia.

Cases Unrelieved by Iodized Oil.—It is instructive to study some of the cases unrelieved by the type of treatment

under consideration. Poor or no results obtained in cases complicated with healed tuberculosis, advanced emphysema, pneumoconiosis, myocarditis and bronchiolar obliteration following irritating gaseous inhalations.

In 3 of our cases, malignancy was found among the asthmatics referred to us in this series, two bronchogenic and one metastatic. These, of course, were not treated. Penta⁹ stated that during the past year, 1936, 14 cases of bronchial carcinoma were found that had been previously diagnosed and treated for bronchial asthma. He well calls attention to the fact that bronchoscopy may be the means of ruling out intra-bronchial pathology, which may be the underlying cause of the asthmatic paroxysms. Two cases of severe asthma in adults associated with attacks of massive lung collapse were unrelieved by iodized oil injections, but following bronchoscopic-suction removal of large, tenacious masses of mucus from lower main lobe bronchi, followed by resumption of the iodized oil injections, were greatly aided as to frequency and severity of attacks.

Four cases unrelieved by the injections over a long period were cured after determining unsuspected allergic irritants and being desensitized to same. One case of papilloma of the right lower lobe bronchus was eventually discovered in a case receiving the injections without relief. Upon bronchoscopic removal, almost immediate cure was obtained. One case not obtaining relief after eight months' treatment with the oil was rechecked. Roentgen study revealed posttracheal pressure from a retrotracheal extension of an enlarged accessory thyroid lobe. Surgical removal of this mass was also immediately curative. One case of luetic infiltration of the peribronchial tissues (tertiary syphilis) was diagnosed after a prolonged course of iodized oil which was of no avail in relieving the symptoms of asthma. Following an intensive antisyphilitic treatment with salvarsan and iodides, this patient was markedly improved. One case in a boy of ten years with typical asthmatic seizures, after no relief with the oil, was found by roentgen and bronchoscopic study to have a small piece of peanut shell lodged in the

opening of the main left upper lobe bronchus, following removal of which attacks promptly ceased.

All of the above cases are from the records of the earliest cases treated in this series in which the presence of asthmatic seizures was considered evidence of bronchial asthma and immediately were placed on the iodized oil treatment.

This but adds to the proof of Jackson's⁵⁴ dictum that "*All is not asthma that wheezes.*" Our earlier experiences lead us to a more serious consideration of the etiological factors in the cases sent to us for treatment and to realize that of course the use of iodized oil in such cases will prove of little or no value.

Thus, in a given series of cases, if certain patients do not respond after receiving the oil for a reasonable length of time, it is advisable to recheck the case by clinical, roentgen and laboratory methods.

Other Respiratory Pathology Accompanying Asthma.

—Aside from the well-known upper respiratory pathology so frequently associated with and considered of etiologic significance in bronchial asthma such as paranasal sinusitis and nasal polyposis, the other bronchopulmonary lesions accompanying asthma consisted chiefly of laryngitis, tracheitis, tracheobronchitis, emphysema, and bronchiectasis. Pulmonary tuberculosis and cases of suppurative pulmonary disease were nil in all of the reports by the various authors quoted in this article. The few cases of hemoptysis noted were considered due to the bronchiectasis.

The chief chest pathology noted, other than that related to the lungs, in the more serious and protracted types of asthmatics is that referable to the cardiovascular system. With advanced myocardial degeneration and its frequent accompaniment, pulmonary edema, particularly at the bases of the lungs posteriorly, one must seriously consider the still further embarrassment of cardiorespiratory function which might result from the indiscriminate injection of iodized oil in already damaged tissues.

Bronchiectasis was present in over 30 per cent of these

combined groups. This was undoubtedly due to the fact that by far the greater proportion of the cases treated were of the chronic intractable type. This was proved by bronchography. The bronchiectasis was of three types, cylindrical, saccular, and mixed or combined types. Most of the cases of asthma, however, were found to be associated with the cylindrical type, involving usually both lower lobes in the chronic type, almost always the lower right lobe; although any one or almost any combination of two or more lobes could be found.

Emphysema was found in over 20 per cent of the cases studied, more marked in the cases of longer duration, and generally bilateral. Foreign bodies were found in the course of preliminary bronchoscopic examination in 9 cases, removal of which immediately was followed by relief of the asthmatic seizures, except in 1 case where marked pulmonary suppuration had already occurred.

Several authors, Anderson¹⁰ and Penta,⁹ noted the presence of a marked laryngitis, tracheitis, or bronchitis. Penta⁹ was struck with the frequency and severity of the tracheobronchitis found during bronchoscopic examination of 75 asthmatics.

Steinburg,⁵⁵ Anderson¹⁰ and myself believe that there is a direct relation between the frequency of the attacks and "the number of plugged tubes" (extent of bronchial obstruction by excessive, viscous secretion).

Summary.—A survey of 1000 cases of asthma of various types reported by eighty-four different observers in various parts of the country, revealed the following facts:

The ages ranged from eight years to eighty-one years.

The duration of the disease varied from two months to fifty-one years.

The average duration of treatment, four months.

The minimum number of treatments needed to relieve was 1 (in 11 cases).

The maximum number of treatments needed to relieve was 80.

The average number of treatments needed to relieve was 32.

The percentage of cases completely relieved was 24 per cent.

The percentage of cases markedly relieved was 34 per cent.

The percentage of cases slightly relieved was 17 per cent.

The percentage of cases not influenced by this method was 25 per cent.

The number of deaths attributable to injection of iodized oil into the lower air passages and reported in the literature were two.

Considering that this series represents nearly 35,000 individual injections of iodized oil, it may be concluded that in the average well-studied case the method is relatively innocuous, but that while serious reactions are comparatively uncommon and fatalities very rare, one must bear in mind the possibilities of same.

With few exceptions, the history of every patient showed an inherited asthmatic background (Anderson¹⁰).

Conclusions.—The direct intratracheal injection of iodized oil offers an additional aid in the treatment of bronchial asthma. It is not a panacea. It is not possible to predetermine what types of cases so treated will be aided, nor what percentage will be symptomatically cured. A gratifying number of patients were absolutely relieved for periods varying from three to seven years; this freedom from the paroxysms equaling, if not surpassing, the length of time obtained by treatment with any other means.

Many of all types of cases that have resisted all other forms of treatment have been completely relieved for prolonged periods, including the allergic as well as the nonallergic types.

Other forms of therapy of proved value in the treatment of asthma must not be disregarded, particularly in those cases in which the use of iodized oil has proved unsuccessful, and vice versa, in cases in which any of the usual methods have been ineffective, the use of iodized oil may prove of signal value. The percentage of successful results seems to depend upon the particular preliminary study of the patients, eliminating those with gross bronchopulmonary pathology, as well as a careful

check-up from time to time by both clinical and roentgen study. In cases not responding after some months of repeated consecutive injections, it is well occasionally to withhold the treatments for periods of from one to even six months, and to then resume the previous routine. The main keynote to success with this method is to individualize each patient and treat him accordingly.

While the beneficial results following the treatment of bronchial asthma by intratracheal injections of iodized oil has been known for over ten years, and encouraging reports continue to appear in the literature, much more research remains to be done, and a consideration of the ultimate results obtained in some thousands of cases considered permanently relieved, one may arbitrarily say, five to ten years after cessation of treatment. As a palliative measure, and occasionally giving startling results, it is a splendid addition to our present limited therapeutic armamentarium for the treatment of bronchial asthma.

CLINIC OF DR. CARL H. SMITH

NEW YORK HOSPITAL AND THE DEPARTMENT OF PEDIATRICS,
CORNELL UNIVERSITY MEDICAL COLLEGE

MANAGEMENT OF NUTRITIONAL ANEMIA IN INFANCY

THE successful management of nutritional anemia in the infant should be directed toward the prevention of the iron deficiency which constitutes its cardinal feature. The prophylaxis of this condition includes supervision of the prenatal period with respect to the prevention and treatment of hypochromic anemia in the mother. Corrigan and Strauss¹ recently reported that this condition could be largely obviated in the mother by the administration of iron during the last four months of pregnancy and it seems entirely reasonable that additions to the prenatal stores of iron may be affected by this means.

With the birth of the infant many procedures have been employed to prevent the abnormal hemoglobin levels that may follow the termination of the period of adjustment. These endeavors are of particular moment with the premature, twin or immature infant, in whom hemoglobin values reach excessively low levels. Prophylaxis of anemia in normal infants was successfully carried out by Helen Mackay² with the routine use of dried milk containing a supplement of iron and ammonium citrate. This has also been accomplished in prematures by Abt and Nagel³ with a combination of the secondary anemia liver fraction and iron, and by Merritt and Davidson⁴ with iron; in both studies the additions were instituted between two and three weeks of life.

The Hemoglobin Determination.—The problem of prophylaxis as well as that of treatment involves an inherent difficulty which arises from the lack of data as to optimum hemoglobin value which will promote the greatest growth and development of the infant. This difficulty is illustrated by the observations of Elvehjem⁶ and his associates who were able to raise the hemoglobin level of infants to values from 12 to 13.5 Gm. per 100 cc. of blood by the addition to their diets of ferric pyrophosphate and copper. In a previous study they had noted values between 11 and 12 Gm. in a group of normal untreated infants from six months to two and one-half years of age. Although the higher hemoglobin content appears desirable, the value for best health has not yet been established. Closely controlled observations would be necessary to determine the advantages of the elevated hemoglobin in the former group over the latter with respect to morbidity, mortality incidence and growth increments.

In the absence of this knowledge, a hemoglobin determination in an infant should be compared with a range of values obtained with infants whose physical development measures up to normal standards. The range of values between 10 and 12 Gm. of hemoglobin per 100 cc. of blood is suggested as a basis of comparison for normal infants from two months of age to the end of infancy, figures already found suitable for patients in the hospital as well as in private practice.

It is at once evident that for routine use, the hemoglobin determination of the blood of an infant must depend upon a simple yet reliable method. Of these, a colorimetric method depending upon the production of acid hematin fulfills these requirements. The Newcomer method, utilizing standardized color disks in a colorimeter, may be used for comparison; or an even simpler method embodies some of the principles of the Sahli method with modifications to increase its precision. This simple method is highly satisfactory if caution is exercised as to the use of standardized nonfading solutions for comparison, as well as an accurately graduated tube and pipette.⁶

For many years I have been using a modified Sahli hemoglobinometer (Hellige type), in which, after dilution of the blood sample, the hemoglobin is read directly in grams from graduations on the tube. With this method, 0.02 cc. of blood from the finger is mixed with the customary 0.1N HCl reaching to the mark 10 on the graduated tube. Placing the tube containing the mixture in hot water (55°–60° C.) for seven minutes has been suggested⁹ as a method to expedite the endpoint. As an alternative, dilution may be postponed for a period of at least twenty minutes to one hour at room temperature. After the maximum color has developed, dilution is carried out carefully with distilled water until the color of the standard is matched. This type of apparatus employs standard nonfading prisms, each one of which is fixed at either side of the tube containing the diluted acid hematin solution in a housing resembling that of the Sahli hemometer. In this type the hemoglobin is expressed as grams per 100 cc. of blood, the standard for 100 per cent being designated as 14.5 Gm. of hemoglobin. It is important to emphasize that it is confusing and unnecessary to compare values obtained for infants with this adult figure. If facilities are available, it is advisable to check this instrument periodically with the oxygen capacity or iron methods, in order to determine whether fading of the standards has occurred. The simplest procedure, therefore, is to express the hemoglobin value as grams per 100 cc. of blood by direct reading from the hemoglobinometer tube and to report it together with the number of grams of hemoglobin normal for the particular age period.

The values for normal infants from the age of two months, the time at which usually the lowest level is reached following birth, remains fairly constant. The range from two months to the end of the first year, according to four recent American studies^{7, 8, 9, 10} of hemoglobin value which are significant because of their close correspondence, is approximately from 10 to 12 Gm. of hemoglobin per 100 cc. of blood, values which are maintained during the second year of life as well. The value of 10 Gm. of hemoglobin may be designated as the

lower limit of normal. Strictly speaking this is an arbitrary figure since it is not unusual to encounter infants, particularly prematures or twins, who are normal in every respect but whose hemoglobin after the second month falls somewhat below this value. In the main, however, the full-term infant of average birth weight whose supervision is placed under the care of the private physician possesses an average hemoglobin content of 11 Gm. or more. The infant whose hemoglobin persistently falls below 10 Gm. on repeated examinations during the first third of infancy requires careful dietary regulation in the subsequent period, often in conjunction with specific anti-anemic therapy.

The clinical appearance of an infant often proves an unreliable index of anemia since pallor may depend upon qualities of the skin such as its texture, racial and familial characteristics, and upon transitory changes in the caliber of the blood vessels.

Whereas with the premature and twin, tests for hemoglobin content should be begun during the second month of life, with the normal full-term infant these may be postponed until the end of the second or third month.

By following closely infants whose hemoglobin content fluctuates about the level of 10 Gm. per 100 cc. of blood, carrying out tests at frequent intervals and instituting anti-anemic therapy if the same or lower values are consistently obtained, treatment is confined to infants in whom the development of iron deficiency becomes apparent and obviates the necessity for routine iron administration to all infants. Particular attention to the hemoglobin level should also be directed to all infants who are growing rapidly; to those who are troubled by frequent infections, even of minor severity; to those whose mothers, during the latter part of pregnancy, were known to have exhibited a profound anemia; and to infants who, during the neonatal period, were suffering from a blood dyscrasia such as primary anemia of the newborn or who have survived the condition of icterus gravis. Infection may result in serious iron deficiencies, manifested not alone

by a diminution in the hemoglobin content but by a decrease in the numbers of erythrocytes and by pronounced changes in their morphologic appearance. Iron therapy is unsatisfactory during the acute stage of the infection, but is effectual during convalescence.

Iron Requirement.—The amount of iron necessary to satisfy the infant's daily requirements has been determined, as in older age groups, by balance studies. Although the iron requirement of the infant has been stated to range as low as 1 to 2 mg. per day,¹¹ even this quantity may be difficult to obtain during the period when milk constitutes the sole article of diet. For preschool children, it has been demonstrated that 0.6 mg. per kilogram of body weight is sufficient for maintenance and growth. The difficulties of absorbing iron from the intestine, and its presence in food partly in a form not available for hemoglobin formation necessitate that infant values at least approximate those of older children. In the final analysis, the simplest index of an adequate iron intake can only be obtained by repeated hemoglobin examinations.

Inorganic Iron Preparations.—With the repeated observation in a specific instance that the hemoglobin fluctuates about the lower range of normal and that at times drops below it, there is a clear-cut indication for iron administration. When this condition exists as well in the older infant who is on mixed feeding, medicinal treatment should likewise be instituted since the results are more rapid. Organic iron preparations are unsuitable for hemoglobin synthesis, whereas the experience of recent years has repeatedly confirmed the striking results with inorganic iron. The choice of an inorganic preparation for the infant, as for the adult, depends upon its acknowledged activity, ease of administration, tolerance, inexpensiveness and solubility. The latter consideration applies particularly to the infant since inorganic salts that are readily ingested by the adult may be unsuitable for the infant. The absorption of iron from the intestine of the infant is subject to a variety of influences; in part similar to those of the adult and in part

resulting from local conditions incident to its own stage of development. The dosage of iron to be administered depends, therefore, on these considerations, so that a specific amount cannot be definitely assigned for a particular age. The dosage should be controlled by frequent hemoglobin estimations, noting at the same time tolerance of the infant for the preparation employed. The dosage of iron must be considered in relation to the iron content of the salt prescribed; these differences being illustrated in the following list of commonly used preparations:

Reduced iron, U.S.P., contains not less than 90 per cent metallic Fe.

Ferrous sulphate, U.S.P., contains not less than 20 per cent Fe.

Ferrous lactate, N.F., contains not less than 19.36 per cent Fe.

Saccharated ferrous carbonate, U.S.P., not less than 15 per cent ferrous carbonate (equivalent to approximately 7.5 per cent iron).

Iron and ammonium citrate, U.S.P., brown scales, contains not less than 16.18 per cent Fe.; green scales, not less than 14.5 per cent Fe.

Ferric pyrophosphate, N.F., soluble scales, contains not less than 10.5 per cent Fe.

Ferric chloride, U.S.P., not less than 20 per cent Fe.

Ferric glycerophosphate, N.F., not less than 17 per cent Fe.

Table 1 gives a partial list of the preparations and their dosage as mentioned in the recent literature.

The choice of an iron salt may be confusing unless it is remembered that whatever inorganic salt of iron is employed, satisfactory results can be obtained with it provided it is prescribed in adequate dosage. With the infant, however, the salt should be preferably soluble so that it may be administered in water, milk or a fruit juice. Reduced iron and saccharated ferrous carbonate possess the disadvantage of requiring suspension because of their insolubility. In recent years iron

TABLE 1
PREPARATIONS AND DOSAGE OF VARIOUS IRON SALTS USED RECENTLY IN NUTRITIONAL ANEMIA OF INFANCY

Iron preparation.	Dosage.	Reference.
1. Iron and ammonium citrate in 10 per cent solution supplemented by 0.5 per cent solution of copper sulphate.	2 cc. of the iron and 1 cc. of the copper solution per kilogram of body weight daily.	Josephs. ¹²
2. Iron and ammonium citrate incorporated in milk, supplemented in some cases by the feeding of extra iron.	4.5 to 9 grains daily, to maximum of 15 grains.	Mackay. ¹
3. Saccharated ferrous carbonate.	30 to 60 grains daily.	Bass and Denzer. ¹³
4. (a) Iron and ammonium citrate. (b) Ferrous sulphate.	Infants 1 to 2 Gm. daily. Children 4 to 6 Gm. daily in sweetened orange juice or water. Infants 6 to 8 grains daily. Children 10 to 12 grains daily.	Blackfan and Diamond ¹⁴
5. Ferric pyrophosphate (10 Gm. are dissolved in 250 cc. of distilled water containing 5 per cent alcohol together with 0.2 Gm. of copper sulphate).	1 teaspoonful given daily. This dose contains 25 mg. of elemental iron and 1 mg. of elemental copper.	Elvehjem, Siemers, and Mendenhall. ⁵
6. Iron and ammonium citrate in 50 per cent aqueous solution.	0.3 Gm. of the salt per kilogram of body weight to premature infants to prevent anemia.	Merritt and Davidson. ⁴
7. Ferric glycerophosphate.	Administered in solution: 10 to 21 grains daily, supplemented in some cases by $\frac{3}{4}$ to $\frac{1}{4}$ grain of copper sulphate.	Usher, MacDermot, and Lozinski. ⁹
8. Ferrous sulphate dissolved in glucose solution.	12 grains daily in divided doses.	Parsens and Hawksley. ¹⁵

and ammonium citrate has enjoyed deserving popularity since widespread usage has confirmed its effectiveness, while its solubility and ease of administration have rendered it especially attractive for infant medication. Iron and ammonium citrate is commonly prescribed in stock solution form usually in a strength of 10 per cent. While this is satisfactory, my practice has been to employ the powdered scales, a small dose of only 5 grains being offered at the start. With the assurance that the medication is well tolerated, the amount is gradually increased. Sweetened solutions of iron kept for any length of time require alcohol as a preservative. When the salt is dispensed in capsules, they are opened before feeding and the contents dissolved in the bottle or glass of milk; or water or sweetened orange juice may be used as vehicles. At times during treatment vomiting, constipation or diarrhea follow the use of the salt, especially if the dose is suddenly increased. Should these untoward symptoms appear, the quantity of iron may be temporarily reduced, following which it may be gradually stepped up to the level necessary to promote hemoglobin regeneration. I have found that in some instances gastric irritation could be related to the fact that the scales of iron and ammonium citrate were not thoroughly pulverized. In the event this cannot be satisfactorily accomplished, reliable proprietary preparations are available in capsule form, each containing 7 to $7\frac{1}{2}$ grains of the salt. In the infant with nutritional anemia of a moderate grade the desired hemoglobin level can be obtained usually with a daily dose approximating 1 grain of iron and ammonium citrate per pound of body weight, totaling 15 to 30 grains. With severe cases in older infants 45 grains and more are at times required, and it is surprising how well these amounts are tolerated. It may be desirable, however, when the dosage appears excessive, either to supplement the iron with traces of copper or to replace the iron and ammonium citrate with another salt, particularly if refusal is encountered.

As already stated, although there is seldom a copper deficiency in hypochromic anemia, instances of nutritional anemia

in infants have been recorded in which the introduction of minute traces of copper to the iron salt resulted in prompt acceleration of hemoglobin production from a previously stationary level. Although the same results may have been accomplished by substituting another iron salt or still further increasing the quantity of the original preparation, the introduction of a small copper supplement should be kept in mind when simple nutritional anemia becomes refractory.

Iron and ammonium citrate may be dispensed with copper sulphate in solution form as follows:

Iron and ammonium citrate	5.0 Gm.
Copper sulphate	0.06 Gm.
Simple syrup to make	60.0 cc.

One teaspoonful of this solution contains approximately 5 grains of the iron salt and $\frac{1}{15}$ grain of copper sulphate corresponding to about 20 mg. of metallic iron and 1 mg. of copper respectively. Recently Fantus¹⁰ has pointed out that syrup of cinnamon of the Sixth National Formulary constitutes an excellent vehicle for iron and ammonium citrate. With the same quantity of the vehicle the iron salt may further be increased to twice or three times in strength (10 Gm. to 15 Gm.) while the dosage of copper remains unchanged. Three teaspoonfuls daily of the largest amount (15 Gm. of iron and ammonium citrate in 60 cc. of the vehicle) prescribed for the infant contains approximately 45 grains of the iron salt and the $\frac{1}{6}$ grain of copper sulphate. The utilization of iron is subject to so many individual factors, however, that an exact dosage cannot be stated but must depend upon repeated hemoglobin estimations.

Although with careful regulation of dosage, ferric ammonium citrate has fulfilled the requirements of a reliable iron salt for the cure of nutritional anemia, recent studies have emphasized the advantages of ferrous compounds. The claims for the latter are based on experimental observations, showing that iron in only the ferrous state is absorbed from the gastro-

intestinal tract and that the potency of any iron salt depends upon the degree to which free ferrous ions are liberated following its ingestion. The greater utilization of iron, as derived from the ferrous salts for hemoglobin formation in hypochromic anemia, has been demonstrated by Witts.¹⁷

Of the ferrous salts, the sulphate has generally been chosen for clinical use—its superiority supposedly resting upon the activity of its ferrous ions and upon the smaller dosage required to secure a therapeutic result as compared with the more complex ferric salts heretofore employed. Its solubility makes it preferable to its earlier bivalent predecessor, saccharated ferrous carbonate. Clinical trial at the hands of many clinicians has already attested to the advantages of the ferrous iron, principally because the hemoglobin level is raised with smaller doses.

It has been pointed out by Parsons and Hawksley¹⁵ that ferrous salts in solution tend to be converted to the ferric form. To prevent oxidation they recommend, as a suitable vehicle for ferrous sulphate, a syrup made by dissolving glucose in water. These authors noted a favorable response in a few infants with only 12 grains daily. Practically, the administration three times daily of a teaspoonful of a solution of 4 Gm. of ferrous sulphate in 60 cc. of glucose solution would assure this intake, although actual dosage can be determined only by progress of the anemia. While the exact strength of the glucose solution required to prevent oxidation is not known, it appears that a concentration above 25 per cent is essential. The ease with which ferrous sulphate undergoes oxidation indicates that its efficacy may depend upon other properties than its supposed ready yield of ferrous ions. Small quantities of this medication should be ordered, otherwise a preservative is necessary. *Powdered ferrous sulphate* may also be dispensed in 3- or 4-grain capsules and administered according to the suggestions mentioned for iron and ammonium citrate. To assure maintenance of its ferrous state, relatively few capsules should be kept on hand at any one time.

In the main, ferrous sulphate has been employed in adults

with hypochromic anemia and there is no reason to expect that it cannot be employed with similar satisfaction in the treatment of nutritional anemia of infancy. Actually the ideal iron preparation for use in infancy has not yet been determined. The most favorable results are obtained by the exercise of skill in the administration of one of the inorganic salts whose activity has been proved by clinical trial.

Diet.—The diminished iron content of milk has led to the suggestion that it be mineralized with iron and copper preliminary to distribution. The milk employed by Mackay,² in which iron and ammonium citrate had been incorporated, served effectively as a prophylactic agent against nutritional anemia. With the means available of detecting the earliest signs of a diminished hemoglobin concentration and the prompt institution of antianemic therapy, this procedure appears unnecessary. The majority of infants, whose diet is adequately supervised and who are free from infection, maintain a level of hemoglobin production well within the normal range. The reason for this probably rests with the earlier introduction of a mixed dietary characteristic of present-day pediatric practice.

Prolonged lactation or an exclusive diet of milk constitutes the outstanding cause of nutritional anemia. Refusal of solid food persisting through the latter half of the first and during the second year of life, has often been productive of such severe anemias that transfusion becomes necessary. At times, the parent or nurse is at fault in that too much reliance is placed upon the conception that milk constitutes a complete food, so that the intelligent persistence in offering solid food is neglected.

Nutritional anemia produced in the infant in this manner is comparable to that of the young experimental animal who is maintained on an exclusive milk diet. The iron from prenatal stores and that derived from blood destruction in the neonatal period vary quantitatively to such a degree with the individual infant that it is impossible to foretell exactly when the introduction of solid food becomes essential. When the blood examination reveals a diminishing hemoglobin content

in an infant after six months, who is refusing solid food, the ingestion of milk requires curtailment. It is at times necessary to reduce the milk intake drastically before solid food is taken by the infant. It should be remembered, however, that the most important factor in the rapid correction of the anemia consists in the administration of medicinal iron in adequate dosage simultaneously with diet changes.

The addition of cereals to the diet between three and four months of age contributes little to the mineral requirements of the infant. With the exception of oatmeal and whole wheat, cereals are notably deficient in iron, since the process of milling deprives the grain of its germ and the outer layers in which this mineral is held. A special cereal mixture* has been devised by Tisdall, Drake and Brown¹⁸ which contains the vitamins and mineral elements including iron in appreciable amounts. While feeding this cereal in the treatment of anemia in the experimental animal has led to contradictory results,^{19, 20} an elevation of hemoglobin was noted when it was included in the diet of older infants and children. Since a primary object in the prevention of nutritional anemia consists in the choice of foodstuffs rich in iron, this special cereal mixture deserves clinical trial to determine its suitability for restoring the diminishing iron reserves of the infant.

Vegetables introduced in the dietary of the infant at about the fifth month serve in a great measure as a source of the constituents essential for hemoglobin synthesis. As already stated, hemoglobin consists of a protein, globin and of hematin; the latter consisting of iron in association with four pyrrole groups. While safeguarding the daily iron intake by the young infant against depletion of iron reserves is undoubtedly accomplished by the adequate intake of vegetables, it is probable that the latter constitute a source of other factors required for promoting blood formation. A recent study by Patek²¹ indicates that the human body can use preformed pyrrole sub-

* This is manufactured by Mead Johnson & Company and is known as Mead's Cereal, and in its dried and precooked form as pablum.

stances, as derived from chlorophyll, for the building of hemoglobin. It is interesting, however, that in nutritional anemia of infancy there appears to be no deficiency in the organic factors as represented by amino-acids and pyrrole substances, since the blood responds rapidly to the addition of sufficient inorganic iron alone. Our knowledge in this respect, however, is still incomplete and the early feeding of vegetables may also serve as a means of restoring diminishing reserves of organic elements.

Solid foods are introduced in the diet of the young infant sooner than formerly, so that cereals are now commonly added at the third month, puréed vegetables, fruits and egg between the fifth and seventh months, and meat by the tenth month. With the realization that this program is empirical and in the endeavor to supply the infant with additional sources of the necessary vitamins and minerals as soon as possible, some of these foods, such as egg, have been included by practitioners at even earlier periods. In recent studies by Schlutz^{22, 23} of the iron metabolism of normal infants who had been fed spinach in addition to the milk formula from the age of five weeks, no beneficial effect was noted upon the iron retention. The diminished secretion of gastric juice in many young infants doubtless influences the impaired absorption of iron despite the most zealous efforts to prepare vegetables properly for infant consumption.

From the classification by Stiebeling²⁴ of a large variety of fruits and vegetables according to their iron content, the following list has been prepared to apply more especially to the period of infancy. Obviously, relatively few of the foods enumerated are adapted for the infant of five months when vegetables are started, but with increasing age and development they can be gradually incorporated in the diet. It is also apparent that many of these foods cannot be consumed in sufficient quantity to satisfy the iron requirement, but they can contribute to it in part when included in the more extensive dietary assortment offered the older infant.

The iron content of the foods in this list is based on the

TABLE 2
IRON CONTENT OF VEGETABLES AND FRUITS
(After Stiebeling²⁴)

EXCELLENT (0.00160 per cent or more)	GOOD (0.00080 to 0.00159 per cent)	FAIR (0.0004 to 0.00079 per cent)
Beans, lima Beet tops Chard Dandelion greens Kale Parsley Peas, English garden Spinach Turnip tops Water cress	Artichokes Asparagus Beans, green string Beets Broccoli, sprouting Cauliflower Escarole Green lettuce Potatoes Blackberries Blueberries Raspberries	Apricots Avocados Bananas Beans, yellow wax Cabbage Carrots Celery, stalk Mushrooms Okra Onions Oranges Parsnips Rhubarb Squash, winter Strawberries Tomatoes Turnips

analysis of the edible portions as prepared for table use. The lack of conformity of iron values, as noted in the determinations of a number of investigators, arises from the multiplicity of methods employed, the preparation of the specimens before analysis and natural variations in the moisture and iron content of different samples of the same food material. In addition to the foods stated, prunes, dates, wheat bran and lentils have been pointed out by other observers as possessing a high iron content.

Of the foods observed by Whipple and his associates^{25, 26} to be potent for hemoglobin regeneration in the experimental anemia of dogs produced by bleeding, liver surpassed all others, beef, calf, pig and chicken liver being equally favorable. Apricots, peaches and prunes were greatly superior to the common vegetables, an observation which was explained by the presence of iron in combination with other important minerals. The remarkable response to liver was attributed not alone to the iron content but to the storage of organic factors concerned with hematopoiesis.

Recent studies have shown that the total iron content of foods does not correspond to its utilization for hemoglobin formation. With the aid of Hill's dipyridyl method, Elvehjem and his associates²⁷ have determined the inorganic iron fraction of various foods. The availability of this portion for hemoglobin regeneration as distinguished from the hematin or organic iron was demonstrated by appropriate feeding experiments with anemic rats. A direct quantitative relationship existed between the amount of iron determined by the reagent and the hemoglobin formation in these animals. The iron composition together with the available fraction of a small group of foods as determined by these investigators is listed in the following table:

TABLE 3
AVAILABLE IRON AS COMPARED WITH TOTAL IRON
(After Kohler, Elvehjem, and Hart²⁷)

Foods.	Total Fe (per gram dry material).	Available Fe (per gram dry material).	Per cent available.
Lima beans.....	0.074	0.054	73
Lima beans.....	0.074	0.052	70
Peas (canned).....	0.122	0.110	90
Peas (fresh).....	0.118	0.085	72
Bananas.....	0.014	0.0086	61
Apricots.....	0.043	0.021	50
Lettuce (Batch 1).....	0.230	0.066	28
Lettuce (Batch 2).....	0.304	0.064	21
Parsley (dried).....	0.304	0.069	23
Spinach (fresh).....	0.352	0.067	19
Beef liver (Batch 1).....	0.260	0.180	69
Beef liver (Batch 3).....	0.181	0.130	72

The availability of iron for hemoglobin formation was also studied by Summerfeldt²⁸ from the standpoint of its solubility. This was estimated from the interaction of various foods with an artificial gastric juice similar in composition and in reaction with that of children between the ages of three and twelve years. The amount of iron brought into solution was found to compare favorably with the fraction utilized for hemoglobin formation as tested in anemic animals. Decreased

solubility values, however, would probably have been obtained on exposure of these foods to a medium similar to that of the gastric juice of infants. The value of foods for their iron content will probably be appraised in the future in relation to the component which is soluble and available for hemoglobin regeneration.

The necessity of copper as an adjuvant to iron in hemoglobin synthesis in experimental animals has been established but whether a deficiency in this element can occur with the ingestion of the ordinary diet has been debated. In the young infant on a sustained milk diet deficient copper stores are conceivable so that copper content of various foods assumes importance. Of 159 samples of common foods analyzed by Lindow, Elvehjem and Peterson²⁹ the copper content ranged from 44.1 mg. of copper per kilogram of fresh calf liver to 0.1 mg. of copper per kilogram of fresh celery. Within this range the following foods may be included as possessing a copper content above the average, and many of them with the proper preparation may be adapted for use during infancy: artichokes, lima beans, oatmeal, mushrooms, wheat bran and wheat germ, apricots, prunes (both dried), calf and beef liver, cod fish, lamb chops, chicken (dark meat) and egg yolk.

Liver may be regarded as the most important food offered to the infant for the prevention and treatment of nutritional anemia for it constitutes a rich source of iron and copper and of organic factors required for red blood cell and hemoglobin formation. The difficulties encountered in feeding adequate amounts of liver, even to older infants, necessitate resourcefulness in its preparation. After a short period of boiling or broiling, it may be scraped, minced or ground; while at times, feeding is facilitated by changing off from calves' liver to beef or chicken liver. The parenteral injection of various fractions of liver and treatment by various concentrates as substitutes for the whole organ are unnecessary, especially when it is realized that the guiding principle in the treatment of nutritional anemia is to overcome an iron deficiency. It should be emphasized that iron in adequate dosage constitutes the most effective weapon

in combating this form of anemia in infants and that it surpasses in potency and in rapidity of action any of the food-stuffs enumerated. The latter are essential, however, as sources of iron to meet the daily requirement and to provide stores for future needs, not alone of iron but of other factors that enter into hemoglobin synthesis.

A discussion of the management of nutritional anemia would be incomplete without mention of the rôle of vitamins and of heliotherapy. It can be said for the former that modern feeding takes cognizance of the need of an adequate supply of the most important vitamins from birth. Severe grades of rickets are at times observed without anemia; on the other hand, rickets may be cured leaving the associated anemia unaffected. Parsons and Smallwood³⁰ have pointed out that, excepting changes produced by hemorrhage in advanced cases of scurvy, there are certain hematologic features which serve to differentiate the anemia of infantile scurvy from those produced by iron deficiency. The ingestion of adequate amounts of the essential accessory food factors is not required for the cure of nutritional anemia, but it is nevertheless contributory toward the state of health essential for the maintenance of a normal hematopoietic balance.

As with the vitamins, it cannot be denied that sunlight exerts a beneficial effect upon the infant although the physiologic processes involved are not always obvious. The lack of exposure to the sunlight does not, however, precipitate nutritional anemia and the studies designed to determine the influences of irradiation upon the hemoglobin and red blood cells have led to contradictory results. In the evaluation of various antianemic agents, ultraviolet irradiation cannot be regarded as a dependable agent either for the amelioration or cure of nutritional anemia in infancy.

CLINIC OF DR. ABRAHAM TOW

NEW YORK POLYCLINIC HOSPITAL AND POST GRADUATE
MEDICAL SCHOOL

THE CARE AND FEEDING OF THE PREMATURE INFANT: WITH SPECIAL REFERENCE TO SIMPLE MILK MIX- TURES

THERE are three important considerations in the care of the premature infant, viz.: nursing, maintenance of body heat and feeding.

A good, careful nurse may mean the difference between life and death. She is worth a dozen incubators. The premature must be watched carefully at all times. Vigilance must never be relaxed, especially during the first two weeks of life. Every detail is important. Handling should be reduced to an absolute minimum. The infant should not be taken out to nurse or lifted from its crib to be fed. Daily weighings are unnecessary. This may be done every second, third, or fourth day, depending upon the condition of the baby. Oil baths can be given every other day. For the first forty-eight hours it may be best to leave the premature absolutely alone except for feeding and to treat symptoms only as they arise. After being oiled at birth the infant should be wrapped in a jacket of cotton wadding and placed in his crib in the Fowler position. The jacket is not absolutely necessary if an incubator is used. The Fowler position is preferred because it is the position favored in cerebral hemorrhage and cerebral hemorrhage is a common finding in these cases. Respiration also seems easier with the head elevated. In this position the infant can more readily be observed. His importance as a sick individual in a crowded nursery is emphasized. Occasionally, edema of the extremities

or scrotum may develop when the infant is kept so for too long a time. Placing him flat on his back will cause a disappearance of this swelling.

Twenty cc. of blood should be given intramuscularly if there is suspicion of cerebral bleeding. In fact, some observers go so far as to advocate the use of blood intramuscularly as a routine procedure in the treatment of all premature infants. Oxygen with from 5 to 10 per cent carbon dioxide or, preferably, oxygen alone is also of distinct advantage. It certainly is indicated when cyanosis is present. A concentration of 40 per cent oxygen is desirable. The oxygen tent is the method of choice but it is not always available. A funnel held close to the nose has given complete satisfaction. Nasal catheters have not proved satisfactory for they plug easily and, if kept for too long a time in the nasal orifices, will injure the delicate mucous membranes.

Maintaining body heat is the second important consideration. This is best accomplished by a mechanical incubator heated with electric bulbs. Such an apparatus is not difficult to construct. Electric bulb heating is preferable to the use of hot water bottles because the latter require frequent changing. The importance of humidity has also been emphasized by Blackfan and Yaglou. In order to determine the optimum environmental temperature and humidity for various groups of premature infants, different fixed percentages of relative humidity were maintained by them in nurseries by means of an air-conditioning system, and the dry bulb temperature was adjusted by trial to the level needed to stabilize the body temperature. At first, relative humidities of 20 and 80 per cent were tried, but later they were changed to 30 and 65 per cent, as it was found that relative humidities above 65 per cent were distressing to the attendants and symptoms of dehydration frequently occurred in premature infants when the humidity was kept below 30 per cent over a considerable period. With a relative humidity of 65 per cent the air temperature required to maintain equilibrium of body heat in infants weighing from 3 to 5 pounds was found to be about 77° F. When the relative

humidity was reduced to 30 per cent, however, it was necessary to increase the temperature to 80° F. Alternate exposures to each of these two air conditions for a week at a time resulted in no significant difference in the stabilization of body temperature. But in prolonged exposures to relatively low humidity, marked differences developed. If kept up for two weeks or longer, it tended to promote instability of body temperature, and general disturbances, such as diarrhea, fever and vomiting, were increased. Gains in weight were generally reduced and fatalities increased. Continuous exposure to high humidity, on the other hand, gave satisfactory results. The effects of intermediate humidities were also studied, but a relative humidity of 65 per cent was found to be more advantageous than any of the other values tried.

With this humidity the temperature requirements ranged from 75° to 100° F., depending on the general condition of the infant and the body weight. Infants under 3 pounds at times required the higher temperatures, 90° to 100° F., to maintain a normal rectal temperature, but this need was often only temporary.

Maintaining a relative humidity of 65 per cent is difficult in nurseries heated by radiators and ventilated by normal means, particularly in cold weather. A large quantity of water must be evaporated to reach this point of humidity and this can be accomplished satisfactorily only by the use of mechanical humidifiers, since the actual moisture content of cold outdoor air is very low compared with what is required indoors. For example, if a room 12 x 15 x 10 feet is to be kept at 77° F. and at a relative humidity of 65 per cent when the outdoor temperature is 20° F. and the outdoor relative humidity 65 per cent it would be necessary to evaporate a minimum of 3 pounds of water per hour in order to maintain the desired humidity. This is with natural ventilation through windows and doors to the extent of about two changes of air per hour. With 25 changes of air per hour, as in Blackfan's investigation, 37½ pounds or 4½ gallons of water must be evaporated per hour to produce the optimum results. From these figures it is

easy to see that evaporation from a pan of water on the radiator, or from a wet sheet, would be entirely inadequate.

A subnormal temperature, particularly in the low weight groups, is a characteristic of prematurity which Blackfan believes should be preserved. Attempts to force the body temperature of these small infants to the supposedly normal level of 98.6° F. should be discouraged as in a number of instances such a practice was followed by overheating with its resultant serious consequences. This view is by no means unanimous as many observers feel that the infant's temperature should be maintained above 98° F. and below 100° F. Naturally, if the temperature rises above this, steps are taken to lower it. Temperatures from 100° to 102° F. for periods as long as twelve hours and more have often been seen in premature infants, however, without deleterious effects. These infants should never be permitted to become chilled as serious consequences may supervene.

FEEDING

In the feeding of the premature, breast milk has been looked upon as the "sine qua non." The doctrine has often been promulgated that it is the only safe food for such infants and that any success with artificial mixtures is solely a matter of luck. Such a belief is a relic of the days when unhygienic methods in the collection, transportation and storage of cows' milk often made it unsafe for human consumption, especially those born before term. These conditions still exist in certain communities, but when one can be assured of clean cows' milk, its use in the feeding of premature infants is safe and, for many reasons, often desirable.

There can be no quarrel with the stand that breast milk is the most desirable food for the normal newborn infant. With the premature certain other factors must be considered. Breast milk is at times difficult to obtain as the child's own mother generally leaves the hospital after two weeks and milk from other patients may not be available. If the mother has to pump her own breasts and deliver the milk, it may be difficult for economic or physical reasons for her to do so. Mothers'

milk may be purchased but it is expensive and such an expense is often a burden to the family. In addition, breast milk containing but 1.5 per cent protein hardly seems suitable for the needs of such a rapidly growing organism as the premature infant. Therefore, in spite of the fact that an imposing array of statistics has been advanced to prove that breast-fed infants are less likely to suffer from respiratory and gastro-intestinal disorders than those artificially fed, it is felt that the sacrifices usually made to obtain breast milk are hardly necessary, especially since adequate substitutes are readily available. Among these substitutes may be mentioned evaporated milk, lactic acid or protein milk mixtures. The feeling has existed that cows' milk could not satisfactorily be used as one of these substitutes but, in our hands, simple mixtures of cows' milk, water, carbohydrate in the form of dextri-maltose, and added protein in the form of calcium caseinate have given complete satisfaction.

During the first week of the premature's existence the important problem is to maintain life, not to produce a gain in weight. One must not try to force fluid intake. Our routine is to start feeding from six to twelve hours after delivery and to give a simple milk mixture, as will be outlined below, every three hours regardless of the weight of the infant and also a 5 per cent sugar solution every three hours. In other words, the infant receives some fluid every one and one-half hours. As the amount of formula taken is increased, the water feedings are decreased. It has been claimed that a premature requires in twenty-four hours about one sixth of its body weight in fluid inclusive of that in milk. However, this amount is not usually taken until well into the second week, sometimes not even until the end of the first month. The appetite of the premature is capricious. The amount taken at each feeding varies, especially during the first fortnight. In the smaller, weaker infants the intake is measured in drachms. One should not attempt to force feeding. One is not dealing with a balloon that has to be blown up. Food is cautiously and slowly increased as the infant evidences a desire to take more. The closer the infant is to term the more he may be expected to take, all other things

being equal. The use of hypodermoclyses to augment the fluid intake is unnecessary except in the exceptional case.

If the infant can suck on a nipple, he is fed in that manner. Otherwise, recourse must be had to a medicine dropper. A soft rubber tubing about three inches long and an eighth of an inch in diameter is attached to the lower end of a long dropper or eye pipet. The soft rubber tubing is inserted at the side of the infant's mouth and passed back to the base of the tongue, about 2 inches from the gum line. After the tip of the tube has reached the posterior wall of the throat, the bulb is gently pressed.

Occasionally, it may be necessary to feed by gavage. This is especially true when feeding produces cyanosis and it is desired to administer food with the minimum of discomfort. For gavage, a No. 12 French catheter may be used. This is marked at three different places: (1) the distance from the tip of the ensiform to the bridge of the nose; (2) 2 cm. above that; (3) 2 cm. above this last mark. When the catheter is passed to the first mark, the tip is from 1 to 2 cm. above the cardia. Feeding may be given then without entering the stomach. The catheter is always passed with the funnel empty. The barrel of an ordinary glass syringe makes a satisfactory funnel. If there is marked distention of the stomach, the catheter is passed to the second mark. Sometimes it is necessary to pass it to the third mark to empty the stomach of air. The average feeding time should be about three minutes. One must be careful to compress the catheter while it is being withdrawn.

Gavage feeding in expert hands may be without danger. One must not forget that it is always possible to enter the larynx and fluid may be accidentally introduced into the lungs. Some observers claim that this happens often enough to warrant the prohibition of this method of feeding. Although it has its advantages, especially in trained hands, we feel that it is not necessary as a routine procedure.

A series of sixteen premature infants under 4 pounds, all of whom had been under our care as private patients, were

recently reviewed to determine the efficacy of simple milk mixtures in the feeding of such infants. Prematures over 4 pounds were deliberately excluded because feeding is usually much less of a problem in the heavier babies and the inclusion of these in a statistical study tends to increase the percentage of favorable results. Five of the 16 failed to survive. Three died within the first twenty-four hours and two expired at the age of six and seven days, respectively. Autopsy failed to reveal findings of significance except prematurity and, in addition, in one infant a subarachnoid hemorrhage was found at the base of the skull. Breast milk was given to all of these. The birth weight varied from 3 pounds to 3 pounds 10 ounces with an average of 3 pounds 4 ounces.

Five infants received breast milk reinforced with 7 to 10 per cent carbohydrate. Simple milk mixtures were gradually substituted after a period varying from three to seven weeks. Chart I illustrates the findings in this series.

The third group consisted of six infants who received milk mixtures commencing six to twelve hours after birth. Chart II best illustrates our results with these infants. Attention is called to the high caloric intake and the high concentration of carbohydrate employed. Sugar was formerly considered a major factor in the production of diarrhea in the infant, but such a premise is no longer tenable and we have found concentrations of carbohydrate from 10 to 17 per cent most helpful in producing weight increases.

Chart III illustrates the type formula used and the rate of increase carried out in feeding these infants. The addition of 1 to 3 per cent protein in the form of calcium caseinate (casec) was thought helpful in stimulating weight increases. The three-hour interval was maintained until a weight of $4\frac{1}{2}$ pounds was reached, when the night interval was increased to a four-hour one. At 5 pounds the four-hour interval was adopted for the entire twenty-four hours and at about $5\frac{1}{2}$ pounds the 2 A. M. night feeding was omitted so that but 5 feedings (q 4 h) were given in the twenty-four hours. Vitamin D in the form of 10 drops of viosterol was given as soon as it was felt that the child

stood a chance of surviving. Orange juice was started at the end of the second month. Egg yolk, cereal and vegetables were added in that order some time between the fourth and sixth months, depending on the child's progress. As soon as possible the 10 o'clock night feeding was discontinued and but 4 feedings given in the twenty-four-hour period. A 3-feed-

CHART III

ing schedule was instituted at the earliest opportunity, usually between the seventh and eighth months, at which time meat was added.

In the feeding of these infants, as well as in the feeding of the normal infant, every attempt should be made to simplify the procedure so that the mother's burden is made as light as possible.

CLINIC OF DR. LUCY PORTER SUTTON

CHILDREN'S MEDICAL SERVICE, BELLEVUE HOSPITAL

THE MANAGEMENT OF RHEUMATIC HEART DISEASE

WHENEVER one becomes interested in a certain disease, it is a great temptation to become so absorbed in it that each observation, new to oneself, seems startling and important. It is a salutary and humbling thing to go back in medical history and learn how long ago physicians equipped only with their senses and with no instruments of precision noted clinical conditions which we are rather wont to consider something new under the sun. Storck, for instance, described rheumatic pleurisy in 1762, and in 1776 Van Swieten recognized that the heart becomes involved in rheumatism. He said, "Sometimes when the pain of rheumatism in the limbs ceases there arises an anxiety of the breast, a palpitation of the heart and an intermitting pulse." David Pitcairn lecturing at St. Bartholomew's Hospital about 1788 taught that acute rheumatism and heart disease were but different manifestations of the same disease. But although study of the heart received great impetus from the invention of the stethoscope by Laënnec in 1819 this conception of heart disease as being an integral part of the picture of rheumatic infection did not receive wide acceptance for many years.

In 1843 Sir Thomas Watson pointed out that children as young as three or four years might develop carditis and said that the earlier they had acute rheumatism the more certainly was the heart involved. Two years later Latham said, "Listen every day to the cases of rheumatic fever, for the endocardial lining may be involved even in the mildest cases." And these

are points which those of us who have studied rheumatic heart disease particularly in children are apt to stress as if it were something of a new idea.

Yet, as far as the human race goes, two hundred and fifty years or so is a short time, and it is during such a period that our knowledge of the clinical aspect of rheumatic fever has become defined, and the sociological importance of the disease has become clear.

In focussing our attention on rheumatic fever, in showing us how to study it, in delineating its complicated features, and in making fundamental studies, there is no one to whom modern medicine owes a greater debt than to Homer Swift.

The title given me to speak on, the management of rheumatic heart disease, is so comprehensive that it will be impossible to cover every important aspect. I shall therefore discuss first the general aspects, and then a few special procedures which we have found useful on the Children's Medical Service at Bellevue Hospital.

I have already said how much was known long ago about the clinical aspects of the disease, and even how some physicians had a conception of it which approximated the present one. The most important advance in recent years is, I think, the realization that the consideration of any aspect of rheumatic heart disease cannot be divorced from a consideration of rheumatic fever as a whole.

It is unfortunate that the care of adults and children should be separated as it is. Certain conditions in infancy and childhood demand special training and experience, and only those who care about children, just because they are children, will become equipped to handle these matters. But when a disease which is not wholly confined to one age group is studied during *one phase by pediatricians and during another by physicians* who handle adults, considerable gaps in the care of the patients are bound to occur. For instance, one of the most important features in the management of rheumatic heart disease is that of the care of ambulatory patients. At Bellevue Hospital there is an adult cardiac clinic run by physicians connected with New

York University. This clinic has a large group of rheumatics and accepts patients over the age of twelve. Our children's cardiac clinic, with the same medical school connections carries a large group of children (between 600 and 700) through the age of sixteen. Some of our children when they reach this age are willing to go to an adult clinic. But many of them become independent, and often resentful of too much supervision. If they feel well they dislike to admit that they have any physical handicap. Consequently in spite of friendly cooperation between the clinics a considerable number of them are lost as to adequate medical supervision during the period of adolescence, a period which must be just as important to them in terms of keeping fit than either early childhood or adult life. Instead of having cardiac clinics it would be more logical to have rheumatic clinics, for the care, as a group, of patients of all ages who have had any form of rheumatic fever. This would lead to better continuity in the observation of patients, and should avoid the loss to medical care of individuals of the adolescent group.

The purpose of a clinic should be two-fold; first the care of the patients, and second the accurate recording of data so that information can be acquired which will lead to better knowledge of the disease and hence better care of the patients. In the relatively short time during which I have been interested in rheumatic fever I have been aware of a change in the general attitude toward rheumatic heart disease. This in New York City has been largely due to the work of the New York Heart Association which has stimulated cardiac clinics to organize on a basis which would contribute to the knowledge of heart disease, without interfering, in any way, with the care of the patients. As a matter of fact, clinics run on such a basis are far more apt to give patients intelligent, conscientious supervision than those less well organized. The extent of the work that the research service does is indicated by the fact that there have been collected 20,000 records of cardiac patients, most of them from 24 clinics in New York City which cooperate with this research service. Analysis of these records is capable of

showing the course of the various heart diseases, and the influence of organized systematic care.

In managing ambulatory patients with rheumatic heart disease two questions must always be uppermost. First, and most important; is the infection active? Second, does the patient show any evidence of heart failure?

The first question, is the infection active, is the most difficult to answer. A frank attack of polyarthritis, or pericarditis, with fever and other evidence of acute infection is simple enough to identify. But we know that many patients who have never had symptoms are found on entering school or when applying for working papers to have definite evidence of heart disease. About 20 per cent of children with heart disease of the rheumatic type in the Bellevue clinic have never been ill with any form of recognized rheumatic infection, and until the chance discovery of heart disease were unaware of the existence of the handicap. This lends emphasis to the belief that a large part of rheumatic infection of the heart is subclinical. In other words, before the inflammatory process in the heart has gone far enough to produce physical signs or definite symptoms of damage, fairly extensive involvement may already have occurred. This fact is reason enough for careful supervision and frequent observation of patients who have ever had any manifestation of rheumatic infection. One should assume, in spite of the absence of proof, that the heart is always involved, even when the manifestation is only chorea. A case occurred on our service at Bellevue a few years ago which brought this point home. A girl of twelve died accidentally toward the end of an attack of chorea. She had had two previous severe attacks, one of them in Bellevue, and had been observed regularly in the clinic. During none of her attacks did she show any of the evidence of what we consider proof of the presence of active infection. She had at no time had fever, tachycardia, elevation of the white blood cells or polynuclears, or enlargement of the heart. She had had an inconstant systolic murmur heard just to the left of the sternum, the type commonly interpreted as being functional or accidental. At autopsy, however, there was endo-

carditis of the mitral valve, and evidence of past inflammation of the aortic valve. Another case was striking in another way. A two-year-old boy had been on the ward with paratyphoid infection—the first illness he had ever had. At that time it was noted that he had an enlarged heart and a loud harsh systolic murmur widely heard but maximum in the third and fourth spaces close to the sternum. A tentative diagnosis of congenital defect of the heart was made. Two days after discharge he was readmitted with high fever and swelling of the back of one hand. Examination of the heart showed no change. His temperature came down and the swelling disappeared, leaving him with the aspect of a poorly nourished, chronically ill child. One day his father brought him a balloon and he played with it rather actively in bed. Soon after he suddenly dropped dead. Autopsy showed extensive endocarditis and myocarditis, definitely rheumatic in type. These two cases are extremes, but show clearly how inadequate are our clinical resources in proving the presence of active inflammatory processes in the heart. Even the erythrocyte sedimentation rate is not an infallible guide; we have had a number of children with active carditis, even pericarditis, who had consistently normal sedimentation rates.

The first step, then, in the intelligent management of rheumatic cardiacs is to realize that active infection may be present without clear-cut evidence. It is the repeated doses of infection, either the subclinical or the acute, which cause eventual deformity of the heart and permanent interference with its functional ability. Once this conception is clearly in mind the importance of identifying rheumatic individuals and of giving them meticulous care during the very beginnings of their disease becomes obvious. What this care should consist of can be stated in very general terms. Since rheumatic fever is an infection the exact etiology of which is still unknown, the best we can do is try to help each individual to keep as close to his optimum state of health as possible in order to increase his resistance to infection. This means attention to his diet, his daily régime, the amount of rest and of recreation he gets. If

he already has heart disease, his activities should be regulated so as nearly to approximate his full capacity, but never quite reach it or to go beyond it. It may mean removing infected tonsils and the care of any other abnormal condition. It means keeping an alert eye for the slightest suspicion of reappearance of the rheumatic infection.

The management of a clinic patient who is suspected of having subacute rheumatic infection is always difficult. He is not sick enough to be hospitalized, and if told to go to bed at home is quite likely to be unwilling to do this. I wish that instead of having cardiac convalescent homes we had institutions designed to take the very early, the subclinical, type for prolonged care such as patients in the early stages of tuberculosis can get. This will probably eventually happen, but not until we get away from the emphasis on heart disease, and think wholly in terms of the rheumatic infection, of which heart disease is the most serious and disabling end-result. Prolonged bed rest under good hygienic surroundings is a primary requirement for the treatment of rheumatic heart disease in its very early as well as late stages.

Little more can be said actually about the management of ambulatory patients. With the exception of digitalis, no drug is of particular importance, as far as the heart itself goes. Secondary anemia which is fairly common in these patients should be treated appropriately. The indiscriminate use of salicylates or similar drugs is to be deplored, since they may mask symptoms which would be important in recognizing activity of the infection. In fact, I think these drugs should never be given over a period of time except when the patient is in bed and under close observation. This is not to say that these drugs are not of great value in the treatment of certain phases of rheumatic fever, but the idea that they should be given over periods of months to ambulatory patients with the idea of preventing recurrences seems to me to be very questionable.

Digitalis is of considerable value in the treatment of ambulatory cardiac patients, even in the absence of auricular

fibrillation, where its value is unquestioned. Several children in our clinic take digitalis regularly. One is a particularly interesting case. She first came to Bellevue at the age of 6 in 1932 in heart failure evidence by cyanosis, tachycardia and great dyspnea. The massive dose method of digitalization caused the signs of failure to disappear, and the heart rate came down to normal. The maintenance dose was discontinued after she had been up and around for a time and she was discharged. She returned in a few weeks again in failure, and the story was repeated a second and then a third time. She is now on digitalis regularly, and as long as she takes 1 cat unit a day she is comfortable, active, attends school and is functionally in class 11A. This is an unusual case, but there are others who with digitalis lead a relatively comfortable life. When the drug is omitted, the heart rate gradually creeps up again and symptoms of failure begin to recur, usually in two to three weeks. These children are given an amount of digitalis necessary for one or two weeks, and return regularly for examination and further supply. They are carefully instructed in the symptoms of overdigitalization and no difficulty has been encountered with this. The need for digitalis only occurs in the rather badly damaged heart, so that it can be thought of almost as a life-prolonging last resort.

Rheumatic patients should be taught to have great respect for colds and sore throats. It happens over and over again that a pharyngitis or tonsillitis in a rheumatic subject is followed in ten days or so by a flare-up of the rheumatic infection. It is quite true that this sequence of events does not always follow but it happens so frequently that one cannot escape the conclusion from purely clinical observation that there is a relationship of some sort. Patients should not only take care of themselves during even a mild cold by going to bed for several days, and perhaps using local treatment, but should avoid possible contacts with individuals who have colds. Following a cold they should be examined carefully for several weeks for evidence of infection. Whether this type of care accomplishes

anything I am not certain, but it is a relatively simple precaution to take.

The management of in-patients with rheumatic heart disease is quite a different matter. They are usually acutely ill, at least when they are first admitted to the hospital, and the relief of symptoms is the first concern. First and foremost, as always, the patients need rest as complete as possible whether they have acute carditis with or without failure. Sedatives or narcotics should be given in sufficient quantity to make the patient quiet and as comfortable as possible. If after a few days the signs of failure have not diminished on rest alone, digitalis should be given. If optimum dosage of this drug is insufficient to control the failure altogether, theocin may be administered. If this is unsuccessful in getting rid of accumulated fluid, a mercurial diuretic may be used. In general, however, if rest and digitalis is not enough, one can assume that there is an extreme grade of myocardial involvement, and that even though the failure is relieved by other means, the prognosis is grave. Congestive failure in itself is a serious manifestation, and there is a limit to the number of attacks which a patient can survive. The greatest number of attacks of congestive failure I have seen occur in one child was eight. This boy was extraordinary from several points of view. He was under close continuous observation from the age of five until his death at eleven, and he had had auricular fibrillation since the age of six and one-half. Each attack of failure occurred following a fresh exacerbation of rheumatic infection, several times while he was taking a maintenance dose of digitalis. He finally died in congestive failure. Only the care which this boy received and the constant use of digitalis kept him alive so long.

Failure is almost certain to follow pericarditis, which is probably the most severe manifestation which rheumatic carditis can take. We now at Bellevue give digitalis at the beginning of an attack of pericarditis with the idea that since signs of failure are practically sure to follow, the failure may be more easily controlled if the drug is given early. This procedure has only been followed for the past year or so, and

whether it is of value in checking the development of the signs of congestive failure cannot be determined until a careful analysis of the records has been made and compared with those of patients not so treated.

The incidence of pericarditis varies from year to year, just as the severity of rheumatic fever varies. Last year, for instance, was a relatively light year at Bellevue, at least among the children, and for the first time in years there were several periods when there were no patients who showed rheumatic nodules. This year on the other hand, the rheumatic season began early with unusually severe attacks of the disease.

For the treatment of the pericarditis, which implies the presence of a pancarditis, absolute rest is essential, with drugs if necessary to secure this. Pain, which is often referred to the left shoulder, is by no means the rule, but when present is controlled better by drugs than by ice-bags or hot water bags over the precordium, although sometimes patients are relieved by these measures.

With rare exceptions, the course of an attack of pericarditis is a stormy one. The patient is acutely ill, and looks like a very sick pneumonia. Sometimes the toxicity of the process is so great that the patient succumbs within a few days, but more often it goes on to the development of pericardial fluid.

This significance of the posterior chest signs developing during pericarditis was brought to our attention by Connor's paper "On the Diagnosis of Pericardial Effusion." He pointed out that these signs indicate the development of a moderate or large amount of fluid in the pericardial sac. Probably some fluid always develops following fibrinous pericarditis, although not always in sufficient quantity to allow an absolute clinical diagnosis. If the fluid develops slowly distressing symptoms may not follow, but more often the patient is made distinctly uncomfortable. Williamson and his coworkers pointed out that sudden death may be due to too great intrapericardial pressure caused by large amounts of fluid and felt that even in rheumatic subjects relief of this pressure by removal of the fluid might be justified. His articles led us to study the matter.

Cohnheim, many years ago had demonstrated that injection of fluid into the pericardial sacs of dogs raised the blood pressure. He was able to cause cessation of the heart beat in these animals by increasing the intrapericardial pressure in this way. When the pressure was decreased by out-flow of the fluid from the sac, the heart resumed beating even though it had been quiescent for two to three minutes. At the same time the blood pressure came back to normal. Because of this work, the investigations of Williamson and others, and our own observation, we feel that the blood pressure can be used as a guide to indicate the necessity for tapping the pericardium. When clinical evidence of fluid begins to appear, the blood pressure should be taken daily, or oftener. If it is rising, if the patient is becoming more cyanotic, weaker, more dyspneic, coughing more, and complaining of a sense of suffocation, and if posterior chest signs have developed we feel that the pericardium should be tapped. Going in posteriorly is as simple and safe a procedure, providing the amount of fluid is large enough to have produced these signs, as a pleural tap. The improvement in the patient's condition, and the relief of distressing symptoms following decrease in the intrapericardial pressure is sometimes very dramatic. After the tap the intensity and extent of the posterior signs may be very much diminished. Although we are not convinced that this procedure makes much difference in the progress of the disease, it has in several instances seemed to be a life-saving procedure, and in all cases, the patients have symptomatically been improved.

Following an attack of acute carditis, the patient, if he survives, goes into the prolonged subacute phase of the infection, which may last for months or years. The evidence indicating the persistence of the active process may be slight, for instance only tachycardia present during sleep as well as during the day, and occasional slight rises in temperature. Or there may be erythema marginatum, or gallop, or loss of weight. Meanwhile, the inflammatory process in the heart is going on, or if gradually subsiding, the healing process of fibrosis is progressing to produce more deformity of the heart structure.

So far, effective therapy at this stage is confined to bed rest plus nursing care, adequate diet and dealing with such factors as the secondary anemia and foci of infection.

It is possible, however, that fever therapy, which in general is indicated in subacute infections which are not virulent enough to stimulate the body's own defense mechanism, may be of value in certain cases. While the value of fever in the treatment of chorea was being investigated at Bellevue Hospital, it was noted that several of the children who had definite evidence of carditis of not severe grade at the same time lost these signs soon after the fever therapy which was given for the chorea. After the observation was first made such patients were watched closely. It was found in the series of 150 children with chorea treated by means of fever that 16 had active carditis. Of these, 9 had lost the signs of activity by the time the treatment for the chorea was finished, and the remainder were clinically inactive within seven to ten days later. As a result of our own observations, we were led to treat with fever therapy a small number of children in the subacute phase of rheumatic carditis. Radiant energy, rather than a foreign protein was used to produce fever. The cases were carefully selected from two points of view. First, since the procedure seemed a rather radical departure, patients who appeared to be in sufficiently good general condition to stand a fever of between 105° and 106° F. for five hours were chosen. Second, only patients with clear-cut evidence of active carditis were treated, since in order to evaluate the results findings which could be said definitely to be present or absent had to be used. Groups of signs such as persistent tachycardia, loss of weight, gallop, fever, nodules, or rash were the criteria used. The few patients who have been so treated have done well. By that I mean that soon after the treatment the signs of activity have either disappeared or noticeably diminished. From only a few cases no conclusions can be drawn, other than that such patients stand fever therapy well, even when there is extensive damage to the heart.

The only reason for mentioning, in a paper of this sort, a

procedure which is entirely experimental is to reemphasize the point that if far-reaching results are to be accomplished therapeutically with rheumatic heart disease, treatment must be directed both toward preventing the development of active infection, and toward inhibiting the process once it has started. Treatment of already established heart disease is almost entirely symptomatic and palliative. While we must, of course, do our best to care for these patients, we should keep constantly in mind the wider viewpoint, the importance of which I have tried to demonstrate.

The death rates from rheumatic heart disease show that it is still a formidable enemy of childhood and adult life, even though the death rates from acute rheumatic fever have steadily declined over a period of years. This probably means that the percentage of the population which is partially incapacitated by this form of heart disease is greater than before. There is, however, some evidence to indicate that organized care, and the increasing interest in rheumatic fever may have had some influence on the death rate in the lower age group. Eventually the proper management of these patients can be defined in much more certain terms than I have been able to do here; but not, I am sure, until the emphasis is consistently put not on rheumatic heart disease, but on the recognition of the presence of the rheumatic infection in its earliest phases; nor until organized care is devoted largely to those rheumatic patients who have not yet developed advanced heart disease.

CLINIC OF DRS. LINN J. BOYD
AND CARL NUSSBAUM

FROM THE DEPARTMENT OF MEDICINE, THE NEW YORK
MEDICAL COLLEGE AND FLOWER HOSPITAL

SOME CLINICAL ASPECTS OF PERIARTERITIS NODOSA

THE tendency to regard periarteritis nodosa as a rare pathological lesion of academic interest is rapidly losing ground. While contributions on its pathogenetic relationship to common disorders (hyperergy, malignant nephrosclerosis, arteriosclerosis, purpuric and erythematous skin lesions) still dominate the literature, increasing attention to its variegated clinical picture and more frequent consideration in differential diagnosis has led to widespread recognition of its practical importance and a rapidly mounting number of correct ante-mortem diagnoses has resulted. As this report is intended to stress clinical aspects, many equally interesting phases have been omitted; moreover, since practically any of the smaller muscular arteries (or groups of arteries) may be affected and since almost every new case presents some unusual features, it has seemed advisable to restrict discussion to the symptoms more frequently encountered. An abbreviated case report follows:

C. S., white male, aged twenty-six, admitted October 26, 1935, died December 9, 1935.

On October 17, 1935, he experienced some pain in the calves which he attributed to bowling. On October 19th, both ankles were swollen and slightly tender. The leg pain increased until he was unable to walk on October 22nd. He had not previously eaten pork and did not work with any heavy metal. His previous history was negative except for pneumonia at eight, tonsillectomy at eleven and an upper respiratory tract infection, one week prior to his present illness.

On admission the physical examination was negative with the following exceptions: slight postnasal discharge and x-ray evidence of frontal and maxil-

lary sinusitis; systolic apical murmur; few discrete shotlike inguinal glands; intense pain on pressure of calves and in popliteal space; moderate swelling of the left wrist.

On November 1st, pain in the lumbar region and insomnia appeared. Routine chest plates revealed an infiltration in the right upper lobe, but there were no confirming physical signs and repeated sputum analyses and gastric lavage for tubercle bacilli were negative. The late afternoon and early evening temperature persisted, varying from 99° to 102° F., with extremes of 98° and 102.8° F. The pulse closely followed the temperature and ranged from 74-120. The minimum blood pressure was 100/60, the maximum 120/74.

On November 12th, there was impaired percussion in the right upper lobe, occasional fine râles; x-ray plates, similar to those previously taken. The Department of Tuberculosis reported that "the clinical picture, physical findings and x-ray films are not consistent with a diagnosis of tuberculosis."

By December 1st, the complaints had disappeared and the patient was mildly euphoric. However, he had lost considerable ground; marked loss of weight, increased cachexia, sallow face; café au lait appearance.

On December 6th, he suddenly became dyspneic and there was an expiratory grunt. Respirations which had been 22 suddenly rose to 44-50. Pulse 104; temperature 100.2° F. The blood pressure rose to 178/110. Râles in the chest became larger and the breath sounds exaggerated. The pulse rate increased (120) and the respirations were shallow and rapid. Death on December 9th.

The following is abstracted from many laboratory examinations:

Muscle biopsy revealed neither parasites nor vascular changes. Inguinal lymph gland biopsy showed "non-specific endothelial hyperplasia." All of many urine analyses showed albumin in increasing amounts; at first occasional hyaline casts, later many hyaline and granular casts; red blood cells in only one specimen. Early blood chemistries were normal; no report on terminal status. Blood Wassermann and gonorrhea complement fixation negative. Many blood cultures negative. Agglutination for typhoid, paratyphoid, and melitensis negative. Red blood cell count showed a gradually increasing hypochromic anemia going from 4,900,000 on admission to 3,332,000 at death. White blood cells on admission 22,000; weekly blood counts showed no change except an unexplained rise to 40,850 the second week of hospitalization and a terminal decline to 16,100. Eosinophiles usually 1 per cent; 3 per cent in one count. Platelets averaged 225,000. One specimen of feces showed ova of *Ascaris lumbricoides*; no other parasites found in several examinations. The sedimentation time gradually increased from 20 to 65 (one-hour readings) during hospitalization. Icterus index 17; van den Bergh—positive delayed. Electrocardiograms negative.

The presumptive clinical diagnosis was: periarteritis nodosa. Terminal bronchopneumonia. The postmortem diagnosis follows (Dr. A. Saccone):

Gross anatomical diagnosis: periarteritis nodosa of internal organs; acute nephritis; peritonitis; hypertrophy of heart with myocardosis; hepatosis; hyperplastic splenitis; chronic vegetative endocarditis; passive congestion of liver with terminal sepsis(?). The *microscopic diagnosis:* renal periarteritis nodosa; periarteritis nodosa of periadrenal tissue and of coronary vessels; old periarterial lesions of liver and pancreas (hepatitis and pancreatitis); passive congestion of liver; hyperplastic splenitis; rheumatic nodule in mitral valve; edema of lungs; hyperplastic adenitis of abdominal lymph glands.

For the purpose of orientation a few remarks on the nature of periarteritis nodosa may be inserted at this point. Periarteritis nodosa is probably not a disease *sui generis* but a hyperergic defensive reaction of the small muscular arteries and arterioles to a variety of releasing toxic and infectious factors. The relative simplicity of the histological structure of arteries results in a rather specific lesion being precipitated by non-specific factors; minor differences in structure, the location and existence of the vasa vasorum, and perhaps of the periadventitial lymphatics probably accounts for the location of the initial lesion and, in part, the type of response. At any rate the hypersensitivity induces an anemic necrobiosis of the medial muscle fibers, the coagulative and hyaline necrosis extending toward the intima and adventitia. Fibrinous and cellular exudation follows and granulation tissue forms. Intimal injury leads to thrombosis and endothelial or subintimal proliferation, to narrowing or occlusion of the vessel lumen with ischemia, infarction and nutritional disturbances in the organ supplied. Or, with persistence of arterial pressure, intimal necrosis, medial hyalinization, and destruction of the elastic lamina, mural tears, false aneurysms, rupture and hemorrhage results. Finally, replacement of the granulation tissue by indifferent fibrous tissue, canalization of the thrombi and perivascular scarring may result in "healing." Apparently the smaller vessels tend to thicken and the larger to rupture.

While periarteritis nodosa has been reported in an infant two and one-half months old and repeatedly in the seventh and eighth decades of life, more than one third of the cases are in the twenty-one to thirty-year period. Approximately 67 per cent of the cases occur in males. As a rule the past history

is singularly free from previous illnesses, although a history of a recent sore throat, "grippe," or upper respiratory tract infection occurs with suspicious regularity; undue exertion and exposure to inclement weather is not unusual. The recent preceding illnesses may have been regarded as trivial and perhaps would have been recorded more frequently if a special search had been made for it. The age, sex, and previous history in this case is illustrative.

Comparatively little is known about the true course of the disease since, until relatively recently, attention has been focused upon obscure and fatal cases. While a division into acute (death in a few days), subacute (death within five months), chronic (year-long duration or recovery) is didactically useful, the impression that a vast majority of the cases terminate fatally within a few months is not necessarily correct. The attempt to create clinical types, for example, gastro-intestinal, renal, neuromuscular, cardiac, cerebral and cutaneous forms, has resulted in some misunderstanding. The disease may remain localized to a single artery, for example, the hepatic or renal, but more commonly various vessels are simultaneously or sequentially affected. Moreover, a patient presenting neuromuscular involvement may suddenly develop a bronchitis, perforation of the intestine, or rupture of a renal artery with an immediate change in the entire clinical picture. This bizarre feature must be emphasized for a false impression could easily be created if one attempted to apply strictly the generalizations which follow in the symptomatology. Any symptom may be present; none are compulsory.

In regard to general impressions, a considerable number of these patients at first are suspected of having an infectious disease. The existence of fever, leukocytosis, tachycardia, increased sedimentation rate and changes in the albumin-globulin ratio support this impression. For this reason trichinosis, rheumatic fever, miliary tuberculosis, and typhoid fever are frequently encountered as erroneous diagnoses. The gradually progressive anemia, the pallor, marked loss of weight and strength may be striking because well-developed and well-

nourished males apparently in complete health are frequent victims. The presence of a syndrome suggestive of subacute sepsis should therefore induce consideration of periarteritis nodosa when an etiological diagnosis cannot be confirmed.

Fever is present in more than two thirds of the cases. Moderate elevations are encountered most commonly and they are often interrupted by afebrile episodes lasting one or more weeks. Recrudescences may be associated with local recurrences of the lesion, extension of the process, complications, or the appearance of skin nodules. The temperature curve does not conform to any particular type, but great irregularity and prolonged spontaneous remissions are suggestive.

The pallor is usually out of proportion to the severity of the anemia; circulatory changes may be partly responsible. Loss in weight and strength, and a cachectic appearance is fairly constant and often marked. Some authors attribute it to an endocrine (adrenal) component.

Recurrent punctate hemorrhages in the skin, at times generalized, and associated with joint pain and swelling are not unusual. This eruption may be accompanied by urticaria. Occasionally lesions resembling erythema nodosum and erythema multiforme may be noted. Nodules may form in the skin, then break down, and form shallow ulcers which heal slowly and recur. In many instances marked involvement of the skin has been associated with a benign course suggesting an esophylactic function of this organ.

Subcutaneous nodules vary from the size of lead shot to a hazel nut. They occur early or late in the course and their appearance is often associated with a recrudescence of fever. Rarely have more than 50 been encountered. At times they are sensitive, soft and elastic. They may disappear within thirty-six hours or persist for years, in the latter instance becoming hard. A careful search should be made for them since it is only by biopsy that the diagnosis may proceed beyond the presumptive stage. Owing to the fact that biopsy is usually performed on the suspicion of trichinosis, most nodules have been reported on the lower extremities. However they

may occur on any part of the body and in one case they were noted on the tongue.

Polymyositis occurs in more than half of the cases; drawing, tearing cramplike pains aggravated by active and passive movement and associated with pressure-sensitive muscles in the neck, shoulders, back, arms and legs is a very common mode of onset. While intermissions occur, muscle involvement usually persists leading to marked weakness and, at times, to decided atrophy of the muscles. When polymyositis is marked, there may be an edema of the overlying skin.

As in this case, the onset may be characterized by pain and swelling of the joints so that rheumatic fever is suggested. Mono-articular involvement is unusual. Salicylates do not seem to affect the symptoms nor the course of the disease.

In contrast to the rarity of central nervous system involvement, the peripheral nervous system is commonly affected. In regard to the former, the brain (and cerebral meninges) rather than the cord reveals the lesion. Isolated cranial nerve paralyses (oculomotor), cerebral hemorrhage and meningism or meningitis may be evident. The polyneuritis is very suggestive from a diagnostic standpoint. Median, radial, tibial or peroneal neuritis may be encountered, and a variety of paresthesias and hyperesthesia may occur. The nerve trunks are often sensitive. While ataxia and tremor do not occur, atrophy, hypotonia, and disturbances of motility are often evident. The tendon reflexes are diminished or abolished. At postmortem, the arteries of the nerves may or may not be affected.

In general the special senses are spared; this is rather surprising since one might expect considerable diagnostic assistance from the eyegrounds. At times blurring of vision is noted and edema of the retina and disk may be seen. When renal lesions occur, and they are perhaps the most constant feature of the syndrome, eyeground findings indistinguishable from ordinary albuminuric retinitis are noted. Marked retinal arteriosclerosis, arteriovenous compression, hemorrhages and "cotton wool" spots are frequent. Vertigo has been recorded

in connection with intracranial aneurysm; the ear seems to escape although bone involvement has been recorded.

The oral cavity, throat and larynx are seldom affected although the nodules have been noted on the tongue. A history of sore throat recently antedating the onset is common. In rare instances muscle involvement has led to disturbances of speech and swallowing.

Although periarteritis nodosa affects the bronchial arteries and pleura, decided respiratory symptoms are usually absent except for bronchitis, pleural effusion and pulmonary edema, which are noncharacteristic and together with pneumonia, are manifested as preagonal phenomena. The predominance of respiratory symptoms and resemblance to pulmonary tuberculosis is rare but not unique to this case. Bloody sputum and chest pain have been prominent features in some cases. It should be added that pulmonary infarction in these cases is usually not recognized and that the pleural effusions and subserous pleural hemorrhages more often are combined with the terminal uremia than with inflammatory processes in the lungs. Bronchial asthma is often recorded in the previous illnesses.

In view of the high incidence of periarteritis nodosa of the coronary vessels it is rather remarkable that cardiac symptoms do not play a greater rôle in the average case. Subjective complaints are not prominent although rarely an anginal syndrome may dominate the picture. Palpitation is an occasional complaint. Dyspnea is common but not characteristic. When prominent it tends to appear late in the course and is associated with left heart failure and the signs of uremia. Cyanosis is usually preagonal. Cardiac edema has been reported but the more common generalized and often transient edema seems to be of renal origin. Cardiac hypertrophy and dilatation are frequently noted. Concomitant endocarditis as well as functional insufficiency may be responsible for the variety of murmurs heard over the apex and base. The murmurs associated with relative insufficiency appear and vanish from time to time without apparent change in the circulation.

The electrocardiogram may reveal changes suggestive of myocardial involvement. It is probable that, perhaps, daily electrocardiograms would aid considerably in the differential diagnosis. At least, changes indicating alterations in the myocardial blood supply, while not peculiar to periarteritis nodosa, do not seem to occur in the diseases with which it is commonly confused. Cardiac irregularities are encountered in rare cases. A pulse rate disproportionately rapid for the temperature is quite suggestive of the lesion and may assist in differentiating it from typhoid. While changes are found in the vagus endings the myocardial changes would seem to be sufficient to account for the tachycardia. In recent years it has become increasingly evident that hypertension has been a seriously neglected symptom. At any rate the occurrence of a rapidly increasing hypertension in the course of a subacute febrile syndrome is peculiar and suggests periarteritis nodosa. It may be worthwhile to stress once again the variability of the picture. Sudden death from intrapericardial hemorrhage due to coronary aneurysm is known in periarteritis nodosa. Likewise instances of gradual cardiac failure have been recorded. Between these two extremes graded transitions occur.

The extreme variations of onset and course is demonstrated even more clearly by the renal involvement. Both extremes are fairly common, namely, sudden onset with massive fatal hemorrhage into the perirenal tissues producing an acute catastrophe, and the gradual development of a true chronic uremia. On the other hand, repeated smaller perirenal hemorrhages are reported as well as an onset with acute convulsive uremia. In addition to the symptoms mentioned above, such as transient edema of the face and extremities, hypertension, etc., evidence of a nephritis is one of the most constant clinical features of the disease while renal infarction is the most common pathological finding. The interlobular arteries are most often involved but in infarction the glomeruli may be affected. Albuminuria is a fairly constant feature of the syndrome; hyaline and granular casts, red blood cells are

found in the urinary sediment. Early, the urine may be scanty when marked sweating is present; later, the total amount falls and the specific gravity tends to become fixed. Simultaneously the phenolsulphonphthalein output falls and the blood chemistry reveals signs of increasing retention. While gross blood in the urine and symptoms suggestive of renal colic are recorded, the renal infarcts are relatively silent. Periarteritis nodosa not infrequently involves the vessels of the pancreas and glycosuria as well as changes in blood sugar may be noted.

Infarction of the testes has been observed occasionally. Complete absence of abdominal symptoms, as in this case, is uncommon. Since periarteritis nodosa affects the gastric, mesenteric, and intestinal vessels in most cases, some symptoms, even if they are not characteristic, are generally present. More than one third of the patients complain of nausea and vomiting; anorexia is even more frequent. About one half of the patients report abdominal pain which may be sufficiently severe to suggest an acute surgical abdomen. In several instances laparotomy has been performed early in the case on the presumption of an acute appendicitis. Save in one instance, the true lesion has not been diagnosed during abdominal surgery. Since infarction of the gastric and intestinal lesions usually results in erosion and ulceration of the mucous membrane and, moreover, since the ulcerations tend to perforate, operation is also performed late in the course of the disease. In a respectable number of cases signs of peritonitis were not manifest during life but a ruptured viscus was found at postmortem. This was suspected in this case when turbid fluid and a dull peritoneal surface were found at autopsy. However, examination of the microscopic sections failed to reveal an actual peritonitis and nothing was found except intense congestion of the entire gastro-intestinal tract.

Pain is usually upper abdominal; in order of frequency it is of epigastric, right and then left hypochondrial localization. Ordinarily the pain is cramplike or colicky in nature. Having appeared, persistence for weeks or months is the rule. Upon palpation, the entire abdomen may be sensitive and some-

what distended. Nodules have been felt in the abdominal wall. At times there is no tenderness in spite of severe pain. Vomiting may precede, often accompany and occasionally temporarily relieve the pain. When intestinal mucous membrane erosion exists, diarrhea and bloody stools are noted. Constipation is about as frequent as diarrhea and the two states may alternate.

The difficulties encountered in correctly appraising the abdominal symptoms are suggestive of the obstacles met universally in this syndrome. Intestinal symptoms may be marked and no lesions found to account for them at post-mortem, marked alterations in the intestinal vessels are also noted with no symptoms having existed during life; finally, the intensity of symptoms may parallel the pathology.

The cystic artery is frequently involved; it may be the first artery affected or at least provocative of symptoms. Inspection of the gallbladder during operation may reveal gross pathology although the true pathology is not realized by the surgeon and usually not by the pathologist until the gallbladder is restudied at the subsequent postmortem. In the syndromes of cholecystitis and dyskinesia of the gallbladder jaundice may be a prominent symptom.

Multiple infarction of the liver is extremely common; it may be partly responsible for some of the hypochondrial pain. But, like infarction of the spleen which also occurs frequently, the hepatic and splenic lesions are usually not suspected. Fairly often the spleen is palpable; although the liver is enlarged in about 25 per cent of the cases, the enlargement is usually not suspected during life.

The superficial lymph nodes are palpable in a respectable number of cases. However, the discrete, noninflamed, painless adenopathy is only moderate and diseases of the lymphatic apparatus rarely come under consideration in the differential diagnosis.

"Chlorotic marasmus," listed by older writers as a cardinal feature of the syndrome, was evident in this case. The hemoglobin is reduced quite regularly and, in most cases, last-

ing more than a few months, the red blood cells reach a level near 3,000,000. Exceptions to this general rule are not infrequent; profuse diarrhea and sweating may retard the appearance of the secondary anemia while massive bleeding or recurrent hemorrhages may accelerate it. In spite of the coexistence of quadrilateral paresthesias and achylia (anacidity or subacidity having been recorded in the few cases in which gastric analysis was done) pernicious anemia is rarely confused with periarteritis nodosa.

The white blood cell count may be normal but usually a moderate leukocytosis exists. Counts of 60,000 have been recorded; more than 30,000 are not unusual but figures near 20,000 to 25,000 are most common. Case histories often provide the impression of a leukocytosis out of proportion to the activity of the "infection," even if it harmonizes with the gravity of the clinical picture. The white blood cells also show a shift to the left. As a rule abnormal forms are not encountered but as high as 10 per cent myelocytes are recorded in the literature. Confusion with diseases of the hematopoietic system does not seem to occur.

An extremely interesting finding is the eosinophilia occurring in about 10 per cent of the cases. As many as 80 per cent eosinophiles have been encountered. This eosinophilia in association with markedly tender calf muscles makes trichinosis the first disease ordinarily considered; but the correct diagnosis is often obtained by muscle biopsies for suspected trichinosis. The eosinophilia occurs in the "absence" of other allergic phenomena such as bronchial asthma and urticaria and seems independent of the type of cellular exudate in the lesion.

In spite of the frequency of purpura, not many platelet counts seem to have been made. Increases as well as decreases have been reported.

Clinical pictures suggestive of sepsis prompt the procurement of blood cultures. Generally speaking these are negative although a variety of micro-organisms, usually streptococci, have been recovered in a minority of cases. Inability

to discover the etiology of an alleged sepsis together with negative blood cultures is suggestive of periarteritis nodosa. Positive blood cultures may lead to premature establishment of an erroneous diagnosis unless it is recalled that periarteritis nodosa may be a nonspecific vascular reaction occurring in conjunction with numerous infections. Gonococcal infection in a few instances seemed to possess etiological significance.

While syphilis is no longer regarded as exclusively responsible it may be an occasional releasing factor. The blood and spinal fluid Wassermann reactions are usually negative; causal connection may not exist even when they are positive. Institution of specific therapy in the syphilitic has occasionally coincided with the onset of the syndrome. Likewise antiluetic therapy alone or in conjunction with x-ray in rare instances was coincident with abatement of periarteritis nodosa. However, temporary spontaneous remissions are quite characteristic of the syndrome. Since with few exceptions only the fatal cases have been well studied and instances of spontaneous recovery have multiplied ever since clinicians became interested in the lesion, it is highly probable that our notions about the mortality are wrong and unrecognized cases with spontaneous recovery may be common.

While the protean character of the syndrome makes brief summarization rather futile, attention to the common clinical features such as inexplicable fever, polyneuritis and polymyositis with muscle atrophy, weakness and emaciation, persistent abdominal colic, edema and hypertension, purpuric eruptions and subcutaneous nodules will facilitate diagnosis, which may often be confirmed by biopsy. Most mistakes are made by not considering the lesion as a diagnostic possibility.

CLINIC OF DR. THEODORE ROSENTHAL

VANDERBILT CLINIC, COLLEGE OF PHYSICIANS AND
SURGEONS, COLUMBIA UNIVERSITY

THE HORMONAL TREATMENT OF ACNE VULGARIS

ACNE is undoubtedly the commonest skin disease of the second and third decades of life. It is estimated that acne patients constitute about 8.5 per cent of all cases seen in dermatologic practice.¹ Its cosmetic importance, however, and its social, economic and psychological implications far outweigh its position as a trivial dermatosis, and bring it to the very forefront of major dermatological problems. Bloch's² summaries of the results of the examination of 4191 children between the ages of six to nineteen years, of both sexes, show that if we consider the comedo the essential lesion of acne, a few such lesions occur in an amazingly high percentage (64 per cent in this series). The percentage of individuals suffering from acne increases with age, and reaches its maximum in the seventeenth year for girls, and the eighteenth year for boys; only 3.4 per cent of girls in that group and 0.6 per cent of boys were entirely free from the eruption.

On the basis, then, of the above figures alone, it would seem that the development of a few acne lesions at the age of puberty is physiologically normal. It is only when the lesions are unusually numerous, severe, or persistent that we can consider acne a disease.

Etiology.—Many attempts have been made to approach the problem of the etiology of acne chemically, metabolically and by histological and bacteriological methods, with, however, little success. On clinical grounds it has long been suspected that acne vulgaris is caused by some endocrine disturbance, presumably by disturbance of the gonads, and many

observers have commented on it. Hollander³ was impressed by the correctness of the conception that the underlying etiologic factor in acne is somewhere in the domain of the endocrine glands, probably the gonads; according to Schamberg,⁴ when the phenomenon of the relapse during menstruation in persons with acne is considered in conjunction with the initial onset of acne at the approach of puberty, the inference appears to be justified that an internal secretion from the sex glands plays an important rôle. Darier⁵ stated that localized acne of the chin in young women is supposed, almost certainly, to indicate utero-ovarian trouble.

Cunningham and Luntsford⁶ conducted an interesting investigation among women college students, comparing 2974 girls with acne, with 3185 who did not have acne as controls. No difference was found in respect to the incidence of common disorders, such as constipation, incidence of colds, state of nutrition as expressed by weight, or conditions of the nose and throat, to which a contributory influence on acne is usually ascribed. No relationship between the presence or absence of acne in the fifteen to thirty-four year age group, and such menstrual characteristics as age of onset, duration, irregularity in interval, amount of pain and flow was demonstrated; thyroid enlargements were found to be associated with a slight increase in acne incidence. In connection with this last finding, it is of interest to note the possibility expressed by Sulzberger⁷ and his co-workers, that increased thyroid activity, frequently coincidental with increased gonad activity and leading to increase in circulating thyroxin (the iodine-containing hormone) might explain acne vulgaris as essentially of the same nature as a very chronic iodide acne. Attempts to prove this experimentally by means of thyroxin patch tests did not, however, lend strength to this possibility.

The work of Stokes and King,⁸ in demonstrating that there is a familial and heritable element in predisposition to acne vulgaris is significant, and important in prognosis and treatment.

The late Bruno Bloch² called acne, among other diseases, a

dysbacterial dermatosis. He noted the fact that eunuchs are said to be immune from acne, and that there have been pathologic cases in which acne appeared in the first years of life when (owing to suprarenal tumor) sexual maturity was precociously developed. In a series of interesting tables and graphs showing the correlation of acne, on one hand, and the commencement of the menses and the appearance of pubic and axillary hair, on the other, he demonstrated clearly that in any age group those sexually developed show a higher percentage of acne than those not sexually developed.

It was Bloch's opinion that acne in its first phase is a consequence of the physiological function of the sex glands, analogous to that which in general we assume for the development of the normal secondary sexual features, such as the formation of terminal hair. The degree of their formation is undoubtedly different. This may be dependent on the fact that the production of sex hormone is varied in strength in each individual, or (and this seems more likely) that the follicular apparatus of the skin (the receptor mechanism) is individually different in its sensibility to this hormone (as for example the type of beard varies in different men). As a result, we are faced by the fact that in acne the normal physiological action of a ductless gland—the sex gland—in the skin leads through transition stages to a final effect which is pathological—a real lesion of the skin, namely acne.

Anatomically, the first changes in acne are a follicular hyperplasia and hyperkeratosis, which is part of the general activation of the pilosebaceous system occurring in puberty. There is usually an accompanying increase in sebaceous secretion. Few patients remain in this stage; most go on to follicular infection and inflammation.

Clinical Investigations.—Until recently there was no means of demonstrating exactly the variations from the normal of the function of any sex gland. The newer knowledge of ovarian function, however, has provided a fairly precise method of determining the excretion of estrogenic substance in blood and urine, both qualitatively and quantitatively.

This was initiated by the studies of Stockard and Papanicolaou,⁹ Evans and Long,¹⁰ and Allen,¹¹ and depends on the fact that synchronously with the cyclical changes that take place in the ovaries, there occurs a cyclical change in the uterus and vagina of the animals used, and that the vaginal secretions partake of this change. The estrogenic substance is concentrated by lipoid extraction of the blood or urine. It is unnecessary here to go into detail regarding the principles and technic of its isolation and recognition. In our work the method described by Kurzrok and Ratner¹² was used for extracting the hormone from the urine, and that of Frank and Goldberger¹³ for extraction from the blood. The vaginal spread of the castrated rat is used as indicator.

For the sake of completeness, although the author has had no experience with it, some mention will be made of the testis hormone. This was recognized by McGee¹⁴ in 1927 in lipoid extracts of the testes. The test for the testis hormone is not as clearly defined, and is slower than that for estrogenic substance in the female, and is accomplished by means of the capon test (comb, wattles and spurs).

It is important, at this juncture, to emphasize the discovery, by Smith¹⁵ and shortly after by Zondek and Aschheim¹⁶ that both ovary and testis remain dormant unless stimulated by the secretion of the adenohypophysis (anterior pituitary or pre-pituitary gland) and that this gonadotropic factor activates alike the gonads of both sexes.

It was thought that evidence of normality of ovarian function would be indicated by a study of the excretion of estrogenic substance in the urine and blood of patients with acne. Kurzrok's¹⁷ studies have shown that normal women between the ages of sex maturity and the menopause excrete from ten to twenty rat units of estrogenic substance per liter of urine throughout the menstrual cycle.

The urines of 34 young women who applied to the Vanderbilt Clinic for treatment of acne were examined. The age range was eleven to thirty-three years, 21 being under twenty years of age.

The results were as follows:	Number of patients	
Strongly positive reaction (10-20 rat units)	6	} 82 per cent
Slightly positive (4 rat units)	1	
Negative reaction	27	

In the blood, the work of Frank and his associates tends to show that in the normal fertile menstruating woman the concentration of estrogenic substance undergoes regular cyclic variations, and also that the renal permeability to these substances varies in the individual. In view of these possibilities it seemed desirable to repeat the above observations, estimating premenstrual values for estrogenic substance in the blood of patients with acne.

In normal fertile menstruating women Frank and Goldberger found one mouse unit of estrogenic substance in 40 cc. of blood taken from the tenth to the third day premenstrually in 44 per cent of their patients, while from the third to the first day premenstrually at least one mouse unit was present in the blood of 100 per cent of the patients. (Average for the entire period 72 per cent.) Neustaedter¹⁹ found estrogenic substance in the blood of 75 per cent of his patients in a similar interval; Mazer and Goldstein²⁰ found the percentage slightly higher in their series (85 per cent).

With these figures representing average norms, we may compare them with the findings in normal menstruating women with acne. Twenty-nine consecutive patients with acne with normal menstrual histories were examined. In none of the patients studied were any other acne-producing factors, dietetic or chemical, detected. Their ages ranged from eleven and one-half years to thirty-four years, and the menstrual interval ranged from twenty-one to thirty-one days. Forty cc. of venous blood obtained within seven days of menstruation was assayed for estrogenic substance by the method of Frank and Goldberger. The results were as follows:

	Number of patients	
Strongly positive reaction (1 mouse unit)	2	} 93 per cent
Weakly positive (less than 1 mouse unit)	16	
Negative reaction	11	

Results of Treatment.—Van Studdiford²¹ treated a number of female patients with acne with a variety of endocrine products, including desiccated ovarian extract, and orchic extract. More recently 15 patients were treated with estrogenic substance, three doses being given by injection on alternate days one week premenstrually. Of these patients, 11 improved. Sixteen patients in another series were treated with a preparation of gonadotropic substance postmenstrually, as a stimulative measure, followed by the injection of estrogenic substance premenstrually, as a substitutional measure. Eight of the patients treated in this manner showed improvement.

Michaels,²² working in cooperation with gynecologists in order to employ the newer endocrine products in the most suitable manner, treated 26 acne patients with hormone therapy. The therapeutic results were poor, and discouraging so far as the influence of the hormone treatment on the acne was concerned.

Lawrence and Feigenbaum²³ treated 6 males and 8 females with pregnancy urine extract, with results sufficiently satisfactory to warrant further study. In a subsequent report Lawrence²⁴ treated a series of 30 patients in the same manner; 10 were regarded as cured, as they had had no relapse two months after treatment had ceased, while 11 were definitely improved.

The patients in my series number 38 females and 2 males, practically all of whom were followed for almost two years. The ages of the female patients ranged from thirteen to thirty-three years, the average age being nineteen and eight-tenths years. Physical examination, apart from the presence of acne vulgaris, was essentially negative in all, except for 2 patients who had pulmonary tuberculosis in arrested stages. One patient showed a basal metabolism rate of +35 per cent, although there were no clinical signs of hyperthyroidism. Seven of the patients were married.

An analysis of the menstrual histories of the patients studied failed to reveal any relation between the acne and any particular menstrual characteristic. A number of the patients

reported premenstrual aggravation of the eruption, while a few thought that it was better at that time.

Treatment consisted of 5 injections of 1 cc. each, of a preparation of estrogenic substance (50 rat units) given at daily intervals, followed by the same number and dosage of a pregnancy urine preparation (containing 100 rat units to each cc.) instituted postmenstrually. This amount of treatment was termed one course. After the next period, a similar course of treatment was administered. During this time no local applications or treatments were prescribed.

The 2 male patients, aged seventeen and eighteen years respectively, were given 1 cc. of pregnancy urine extract three times weekly for several weeks; one made a speedy and complete recovery, while the other showed no improvement.

The results of treatment of the female patients are as follows:

	Number of patients	Average number of courses per patient
Definitely improved	13	2.3
Slightly improved	10	1.8
No improvement	15	1.4

It is evident that the total amount of treatment administered bears a definite relation to the end-result, as the patients who improved received almost twice as much as those who did not (2.3 courses compared with 1.4).

In connection with this type of therapy, it is pertinent to call attention to the possible ill-effects attending prolonged treatment with estrogenic substances. Kunde *et al.*²⁵ in 1930 showed that continued high dosage of estrogenic substances has a distinctly sclerosing effect on the ovaries. Numerous reports have also appeared relating to the carcinogenic properties of estrogenic substances; one observer²⁶ states that mammary cancer developed in male mice following treatment with these substances, while others saw atypical growths, resembling cancerous changes in the uterine cervix of monkeys after prolonged treatment. Recent biochemical studies of Dodds,²⁸ and

Merrian,²⁹ among others, have demonstrated the close chemical and biological relationships between carcinogenic compounds and estrogenic substances; both contain a phenanthrene nucleus and possess the property of follicular irritation.

Comment.—The treatment of acne is still a problem, mainly as a result of uncertainty as to its cause; roentgen therapy, formerly regarded as a specific, has not proved completely satisfactory in all cases, although it is undoubtedly the best single and the most certain means of treatment available. McKee and Ball³⁰ obtained complete clinical cures in about 83 per cent of their cases with x-ray; Lord and Kemp³¹ found about 75 per cent of their patients cured, and Michael³² had final success in about 85 per cent of his patients with x-ray treatment. It is in the group of approximately 20 per cent of x-ray failures that one must consider an alternate form of therapy. It is the disappointing experience of every dermatologist to see relapses or recurrences in patients who have had maximal amounts of roentgen irradiation; among other forms, surely treatment with hormone preparations has a definite place.

It is believed that on the basis of the foregoing investigations one may assume that a definite relationship exists between the estrogenic hormone and acne, and that a deficient secretion of this hormone may prove to be the direct or indirect factor in the causation of one type of acne. While it is known that the anterior pituitary gland governs or regulates gonadal activity no information is available as to the apparent dysfunction, if any, in the link between it and the ovary. In this connection a possible, although remote, explanation of part of the improvement following roentgen irradiation may be attempted. It is conceivable that, in the course of routine roentgen therapy for acne, the pituitary gland is affected by the irradiation administered, and, in consequence, induces a normal gonadal response.^{33, 34}

The evidence is strong, then, that one type of acne is caused by disturbance of the sex endocrines. Just what that disturbance is, or how it acts, is not clear. Endocrine therapy

for acne is not yet completely reliable because we do not know the best preparations to use, or how to administer them. At the same time in addition to any so-called "specific" therapy, an appreciation of the secondary factors involved in the management of any acne patient is very important; these have been clearly outlined by Wise and Sulzberger,³⁵ and need no re-emphasis here.

Conclusion.—Estimation of estrogenic substance in the urine and blood in two independent series of females with acne yielded parallel results: 82 per cent of patients showed absence or subnormal quantity in the urine, and 93 per cent showed absence or subnormal quantity in the blood.

This leads to the belief that associated with acne there is abnormality of formation or of utilization of the sex hormone. The exact nature of this aberration and the direction it takes are unknown. It is as yet undetermined whether lack of estrogenic substance or some other basic fault is the cause of acne.

Treatment of these patients with preparations of estrogenic substance and gonadotropic substance, as outlined above, produced some favorable results (60 per cent improvement). This may be compared with the results obtained with x-ray treatment, about 80 per cent.

Prolonged treatment with estrogenic substances is not without danger; sclerosis of the ovaries, and carcinogenesis have been reported.

The basic principles underlying the general management of patients with acne must not be overlooked, regardless of what specific therapy may be employed.

CLINIC OF DRS. MARION B. SULZBERGER
AND JOSEPH GOODMAN

SKIN AND CANCER UNIT, NEW YORK POST-GRADUATE MEDICAL
SCHOOL AND HOSPITAL OF COLUMBIA UNIVERSITY

TUBERCULODERMS

THE dermatologic manifestations of tuberculosis are diverse and protean. All are due to the effects of the tubercle bacillus, but it would, indeed, represent a great step backward to be content to call these many different and distinctive manifestations all simply "tuberculosis of the skin."

It is particularly the studies of Wolff-Eisner, and of J. Jadassohn, Lewandowsky, and Martenstein, and their school that have demonstrated that a large part of the variability in the morphea and the course of the various types of skin tuberculosis is dependent upon local immune-biologic alterations of response (allergy) on the part of the tissues of the host.^{1, 2, 3, 4, 5, 6} Such fundamental immunologic studies on a dermatologic object inevitably bring to light basic principles applicable to resistance and infection in general. For example, there can be no doubt that further study of pulmonary and other internal tuberculosis will eventually demonstrate a similar influence of immunologic forces and possibilities of immune-biologic classification.* These points are well illustrated in two excellent papers by Max Pinner, in the first of which⁷ the question of the influence of allergy (*i. e.*, altered

* Some of our recent immunologic studies on the tuberculoderms were made possible by a grant from The Hofheimer Foundation of New York City, and we take this opportunity to express our appreciation of this generous contribution.

responses) is discussed in relation to the course and immunity of pulmonary tuberculosis, and in the second of which⁸ attention is called to a relatively benign and a-bacillary form of hematogenous nonmiliary pulmonary tuberculosis. It seems possible that some of the cases he describes are analogous to sarcoids; are, perhaps, actually isolated "sarcoid" disease of the lungs, appearing without skin sarcoids. It would be of interest to know the reaction of Pinner's 28 cases to intracutaneous quantitative tuberculin tests. We believe that in some, at least, such tests might possibly bring to light a specific anergy; and thus might practically establish the absolute immunologic relationship of the cases to Besnier-Boeck's disease and to the sarcoid forms of skin tuberculosis.

General considerations of this nature constitute, perhaps, the main reasons for preserving the knowledge that has already been gained; and for continuing to maintain the clearest possible distinction between individual tuberculoderms. In addition to general reasons, however, there is a more specific reason for interest in immune-biologic phenomena in relation to tuberculosis of the skin. A rational immunobiologic classification of value is possible not only because of definitions, terminology, and mutual understanding, but, also, because of the indications furnished for proper management and therapy, as well as for the determination of prognosis in the individual case.

It is the purpose of this contribution to resubmit—though only schematically and concisely—the classification of tuberculoderms that today enjoys the most widespread general acceptance, and which is essentially that of the Jadassohn-Lewandowsky school.

Since a division into various categories ultimately depends upon biologic, and particularly upon immune-biologic phenomena, it is self-evident that the lines drawn cannot have mathematical precision. There must be overlapping and transitional forms; exceptional and unclassifiable cases; and cases which seem to violate any and all rules. In spite of the exceptions, however, the classification offered has stood the test

of time, and has shown itself to be practically and theoretically indispensable.

Although many of the essential characteristics of the common tuberculoderms have been known for more than thirty years, nevertheless there still exists, unfortunately, not inconsiderable confusion in regard both to the concepts and to the terms forming the basis of a rational classification of skin tuberculosis.

Three points in particular seem to give rise to misunderstanding. The first of these is the meaning of the phrase, "*primary* tuberculosis of the skin," the second is with regard to the definition of "tuberculid," and lastly the loose employment of the words "tuberculous," "tubercle," "tubercular," and "tuberculoid."

Primary tuberculosis of the skin designates only those skin conditions which result when the tubercle bacillus invades the skin of an individual never before infected by this micro-organism, either in the skin or in any other organ. This occurs only when there is a first tuberculous inoculation of the skin in a person previously entirely free from tuberculosis.

Obviously, primary tuberculosis of the skin must occur predominantly in infants and young children, in whom there is less likelihood of an earlier pulmonary, gastro-intestinal, or other internal infection, and it is, therefore, relatively rare. It can occur only on areas exposed to external infection; and the bacilli causing the lesion must necessarily, directly or indirectly, emanate from some other host.

The two well-known representatives of primary skin tuberculosis are:

1. Massive infection in the very young infant (E. Wolff, G. Fedders, and others²) following ritual circumcision. This type of infection produces a rapidly growing ulcer, and frequently terminates fatally.⁹ Fortunately, this form is almost an entity of the past.

2. A small, hard, indolent ulcer with marked, nontender regional lymphadenopathy—usually seen in children. The picture so closely simulates primary syphilis that it is usually

at first diagnosed as syphilis and it has, indeed, come to be known as tuberculous chancre or chancriform tuberculosis.^{10, 11, 12, 13, 14}

All of the other forms of skin tuberculosis are not to be classed as *primary*, for they represent superinfection or reinfections in the immunologically altered skin of *previously infected* individuals (regardless of the site of the previous inoculation). This immunologic alteration of the skin persists in most instances, and is generally present irrespective of the state of activity or healing of the primary, internal or other focus. Therefore, no primary tuberculoderm can later occur in an individual who was at any time previously inoculated with the bacillus.

Tuberculids.—There are some who would place the words “tuberculosis” and “tuberculid” in sharp contrast to each other; would even make these two terms mutually and reciprocally exclusive. This is obviously impossible. All tuberculids are tuberculosis; just as all syphilids are syphilis; and just as all dermatophytids are manifestations of dermatophytosis. “Tuberculosis” is the inclusive term, and means simply a pathologic process due to the effects of the tubercle bacillus. “Tuberculid,” on the other hand, refers to certain skin manifestations of tuberculosis characterized by the presence of a group of fairly distinctive criteria.

To be termed a tuberculid, a manifestation must conform to the following criteria:

1. It must be secondary in the sense that it must be due either to bacilli or to the products of bacilli or to both, emanating from a focus elsewhere in the same individual.

2. It must differ somewhat in nature from the distant focus, this difference being largely attributable to the immunobiologic alteration of the tissue in which the tuberculid appears. But the tuberculid differs from the lesion of direct inoculation, not only because it appears at a later date in a skin already immunologically “prepared,” but also because it has an entirely different pathogenetic mechanism from that of

the primary lesion or of the exogenous local superinfection or reinfection.

There are further characteristics suggestive of an "id." Although an "id" may occasionally be lymphogenous in origin, or may arise even by contiguity, it is of *hematogenous* origin in the overwhelming majority of instances. Furthermore, "ids" usually appear in showers, symmetrically disseminated, and generally without constitutional symptoms. Moreover, the individual lesion of an "id" does not usually continue to grow greatly toward the periphery, but is confined to the original area or its immediate vicinity. In addition, it is very likely to heal spontaneously.

In many forms of tuberculids, the immunologic alteration manifests itself by causing either a very rapid destruction or attenuation of the bacilli which may have arrived at the site; the altered response of the tissues is further made evident by the altered histopathologic picture in which specific tubercle formation (*i. e.*, the formation of fully developed, characteristic tubercles) may be either in the background or entirely absent.

We wish expressly to emphasize that the concept "tuberculid" does not imply that the lesion has been caused by non-living bacillary products alone; and thus does not imply that no living organisms have been or are actually present at the site of the lesion. While it was originally believed¹⁶ that living organisms were never present, and that "ids" were produced exclusively by the products of organisms, this idea was almost immediately proved to be erroneous, and was soon discarded.^{16, 17, 18, 19} (See Goldsmith²⁰ for a discussion of theories concerning attenuated bacilli and filter-passing forms.) The concept of the purely toxic nature of any "id" is today entirely untenable, "for it has been proved time without number that living micro-organisms are demonstrable (at the proper time and with the proper technic) in practically all 'ids.'"²¹

Although the histologic structure of a tuberculid may contain typical tubercles (as, for example, in lupus miliaris disseminatus faciei), it may be merely tuberculoid (as in the

naked epithelioid tubercle of the sarcoids), or it may be, to a great degree, nonspecific (as in certain cases of tuberculosis indurativa and tuberculosis papulonecrotica); or the histology may present combinations of all these forms.

Tuberculous means "due to the action of the tubercle bacillus"; as in tuberculous disease, which includes any manifestations due to the mycobacterium tuberculosis; tuberculous tissue thus meaning the tissue found in any type of tuberculosis.
